In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is characterized by signs of severe illness, organ dysfunction, or a high parasite load (peripheral parasitemia greater than 5% or greater than 200,000 parasites/mcL). It is principally a result of *P falciparum* infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen.

Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe hemolysis; hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria and severe anemia. Cerebral malaria is a consequence of a single severe infection while severe anemia follows multiple malarial infections, intestinal helminths, and nutritional deficiencies. In a large trial of African children, acidosis, impaired consciousness, convulsions, renal impairment, and underlying chronic illness were associated with poor outcome.

Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly

▲ **Figure 35-2.** Thin film Giemsa-stained micrograph with *Plasmodium falciparum* ring forms. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

▲ **Figure 35-4.** Thin film Giemsa-stained micrograph with *Plasmodium vivax* schizont. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

and, with *P. malariae* infection, immune complex glomerulopathy with nephrotic syndrome. HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

B. Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis (Figures 35-2, 35-3, 35-4, and 35-5), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals, although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears at 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially greater than 10–20% of erythrocytes infected or greater than 200,000–500,000

parasites/mL) or the presence of malarial pigment (a breakdown product of hemoglobin) in more than 5% of neutrophils is associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple “dipstick” format. These tests are not well standardized but are widely available. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform. However, *P. falciparum* lacking the most common rapid diagnostic test antigen, histidine-rich protein 2 (HRP2), has been identified in some areas, leading to concern that HRP2-based tests may miss some cases of falciparum malaria.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR and related molecular tests (eg, LAMP) are highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are not routinely treated, are common.

▲ **Figure 35-3.** Thin film Giemsa-stained micrograph with *Plasmodium malariae* trophozoite. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

▲ **Figure 35-5.** Thin film Giemsa-stained micrograph with *Plasmodium ovale* trophozoite. (From Steven Glenn, Laboratory & Consultation Division, Public Health Image Library, CDC.)

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

► Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in non-immune individuals.

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

A. Non-Falciparum Malaria

The first-line drug for non-falciparum malaria from most areas remains chloroquine. Due to increasing resistance of *P vivax* to chloroquine, alternative therapies are recommended when resistance is suspected, particularly for infections acquired in Indonesia, Oceania, and South America. These infections can be treated with artemisinin-based combination therapies (ACTs) or other first-line regimens for *P falciparum* infections as discussed below.

For *P vivax* or *P ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase [G6PD] deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated. Tafenoquine, which is related to primaquine, appears to offer similar efficacy with simpler dosing, but it also engenders potential toxicity in those with G6PD deficiency, and it remains under study. *P malariae* infections need only be treated with chloroquine.

B. Uncomplicated Falciparum Malaria

P falciparum is resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the exceptions of Central America west of the Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding chemoprophylaxis should follow the same geographic considerations.

ACTs, all including a short-acting artemisinin and longer-acting partner drug, are first-line therapies in nearly all endemic countries. WHO recommends six ACTs to treat falciparum malaria (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Quinine generally remains effective for falciparum malaria, but it must be taken for 7 days and

Table 35–2. Major antimalarial drugs.

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine ¹	4-Aminoquinoline	Treatment of <i>Plasmodium falciparum</i> , optimally in fixed combination with artesunate
Piperaquine ¹	4-Aminoquinoline	Treatment of <i>P falciparum</i> in fixed combination with dihydroartemisinin
Quinine	Quinoline methanol	Oral and intravenous ¹ (for severe infections) treatment of <i>P falciparum</i>
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> ; alternative for malaria chemoprophylaxis
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of <i>P falciparum</i> , optimally in combination with artesunate; intermittent preventive therapy
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine ¹	Phenanthrene methanol	Treatment of infections with some chloroquine-resistant <i>P falciparum</i>
Lumefantrine	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Pyronaridine	Benzonaphthyridine	Treatment of <i>P falciparum</i> malaria in fixed combination artesunate
Artemisinins (Artesunate, artemether, dihydroartemisinin)	Sesquiterpene lactone endoperoxides	Treatment of <i>P falciparum</i> in oral combination regimens for uncomplicated disease and parenterally for severe malaria

¹Not available in the United States.

Table 35–3. WHO recommendations for the treatment of uncomplicated falciparum malaria.

Regimen	Notes
Artemether-lumefantrine (Coartem, Riamet)	Coformulated, first-line therapy in many countries. Approved in the United States.
Artesunate-amodiaquine (ASAQ)	Coformulated, first-line therapy in multiple African countries.
Artesunate-mefloquine	First-line therapy in parts of Southeast Asia and South America but efficacy decreasing in parts of Thailand.
Artesunate- pyronaridine	Coformulated. Most recently approved regimen; used in some Southeast Asian countries.
Artesunate-sulfadoxine-pyrimethamine	First-line in some countries, but efficacy lower than other regimens in most areas.
Dihydroartemisinin-piperaquine	Coformulated. First-line in some Southeast Asian countries but efficacy decreasing in parts of Cambodia.

Data from World Health Organization: Guidelines for the Treatment of Malaria. World Health Organization. Geneva 2015.

is poorly tolerated, and should best be reserved for the treatment of severe malaria and for treatment after another regimen has failed (Table 35–4).

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be admitted to the hospital due to risks of rapid progression of disease. A number of options are available for the treatment of uncomplicated falciparum malaria in the United States (Table 35–4).

C. Severe Malaria

Severe malaria is a medical emergency. Parenteral treatment is indicated for severe malaria, as defined above, and with inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals.

The standard of care for severe malaria is intravenous artesunate, which has demonstrated superior efficacy and better tolerability than quinine. In the United States, intravenous artesunate is available on an investigational basis through the CDC (for enrollment call 770-488-7788); if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinine (available in most countries but not the United States) or quinidine (available in the United States). In endemic

regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective. Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia.

Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and hemofiltration or hemodialysis. With high parasitemia (greater than 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated and it is generally no longer recommended.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine remains the drug of choice for the treatment of sensitive *P falciparum* and other species of malaria parasites (Table 35–4). Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so it must be used with primaquine to eradicate *P vivax* and *P ovale* infections. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal and Hispaniola. Chloroquine-resistant *P vivax* has been reported from a number of areas, most notably Southeast Asia and Oceania.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events.

2. Amodiaquine, piperaquine, and pyronaridine—Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and artesunate-amodiaquine is one of the standard ACTs recommended to treat falciparum malaria (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that has been coformulated with dihydroartemisinin in an ACT. Piperaquine appears to be well tolerated and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum and vivax malaria. Due to the long half-life of piperaquine (~3 weeks), dihydroartemisinin-piperaquine

Table 35–4. Treatment of malaria.

Clinical Setting	Drug Therapy ¹	Alternative Drugs
Chloroquine-sensitive <i>Plasmodium falciparum</i> and <i>Plasmodium malariae</i> infections	Chloroquine phosphate, 1 g at 0, followed by 500 mg at 6, 24, and 48 hours or— Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours	
<i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections	Chloroquine (as above), then (if G6PD normal) primaquine, 30-mg base daily for 14 days	For infections from Indonesia, Papua New Guinea, and other areas with suspected resistance: therapies listed for uncomplicated chloroquine-resistant <i>P falciparum</i> plus primaquine
Uncomplicated infections with chloroquine-resistant <i>P falciparum</i>	Coartem (artemether 20 mg, lumefantrine 120 mg), four tablets twice daily for 3 days or— Malarone, four tablets (total of 1-g atovaquone, 400-mg proguanil) daily for 3 days or— Quinine sulfate, 650 mg three times daily for 3–7 days Plus one of the following (when quinine given for < 7 days) Doxycycline, 100 mg twice daily for 7 days or— Clindamycin, 600 mg twice daily for 7 days	Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours or— Dihydroartemisinin-piperaquine ² (dihydroartemisinin 40 mg, piperaquine 320 mg), 4 tablets daily for 3 days or— ASAQ ² (artesunate 100 mg, amodiaquine 270 mg), two tablets daily for 3 days
Severe or complicated infections with <i>P falciparum</i>	Artesunate 2.4 mg/kg intravenously every 12 hours for 1 day, then daily ^{3,6}	Quinidine gluconate, ^{4–6} 10 mg/kg intravenously over 1–2 hours, then 0.02 mg/kg intravenously/min or— Quinidine gluconate, ^{4–6} 15 mg/kg intravenously over 4 hours, then 7.5 mg/kg intravenously over 4 hours every 8 hours or— Quinine dihydrochloride, ^{2,4–6} 20 mg/kg intravenously over 4 hours, then 10 mg/kg intravenously every 8 hours or— Artemether, ^{2,6} 3.2 mg/kg intramuscularly, then 1.6 mg/kg/day intramuscularly

¹All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See Centers for Disease Control and Prevention's guidelines (phone: 877-FYI-TRIP; <http://www.cdc.gov/malaria/>) for additional information and pediatric dosing.

²Not available in the United States.

³Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

⁴Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.

⁵Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

⁶With all parenteral regimens, change to an oral regimen as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.

offers the longest period of posttreatment prophylaxis of available ACTs. However, resistance to piperaquine has emerged in southeast Asia, with consequent treatment failures of dihydroartemisinin-piperaquine in that region.

Pyronaridine is a benzonaphthylidene that was also previously used as a monotherapy to treat malaria in China and acts against many drug-resistant strains of *P falciparum*. The combination of artesunate plus pyronaridine has shown excellent efficacy against falciparum and vivax malaria and has been well tolerated, although elevated transaminases can be seen.

3. Mefloquine—Mefloquine is effective against many chloroquine-resistant strains of *P falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand).

For treatment of uncomplicated malaria, mefloquine can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate as an

artemisinin-based combination therapy (ACT) for falciparum malaria, although resistance limits efficacy in Southeast Asia. It should be taken with meals and swallowed with a large amount of water. Mefloquine is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash and, uncommonly, seizures and psychosis. There is an FDA black box warning about neuropsychiatric toxicity, possibly including rare, irreversible effects. Mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if these drugs are used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

4. Quinine and quinidine—Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy (Table 35–4). Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria.

Resistance of *P falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is the standard of care. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to an oral agent as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is an alternative first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances.

Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, but dangerous arrhythmias are uncommon when the drugs are administered appropriately. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine.

5. Primaquine—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale* (Table 35–4). Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or quinine. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes. As a new strategy to lower transmission, a single low dose of primaquine in conjunction with an ACT to treat uncomplicated falciparum malaria was well tolerated and lowered transmission to mosquitoes in subjects with normal G6PD levels.

For *P vivax* and *P ovale* infections, chloroquine or other drugs are used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine (52.6 mg primaquine phosphate [30 mg base] daily) is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of *P vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine, and the drug may fail to eradicate liver forms.

Standard chemoprophylaxis does not prevent a relapse of *P vivax* or *P ovale* infections, since liver hypnozoites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area. Primaquine can also be used for chemoprophylaxis to prevent *P falciparum* and *P vivax* infection in persons with normal levels of G6PD.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

6. Inhibitors of folate synthesis—Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), are used, generally in combination regimens, for the treatment and prevention of malaria, although the drugs are rather slow acting and now limited by resistance.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). It is no longer advised for chemoprophylaxis due to rare serious side effects with long-term dosing. For treatment, advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance is now a major problem.

Sulfadoxine-pyrimethamine plus artesunate has shown efficacy for malaria treatment in some areas but is best replaced by more effective ACTs. Sulfadoxine-pyrimethamine is recommended by WHO for monthly preventive therapy in pregnant women in areas of high endemicity, although its efficacy is limited by resistance. Amodiaquine plus sulfadoxine-pyrimethamine is recommended monthly during the rainy season for chemoprophylaxis in regions of West Africa with seasonal malaria transmission and limited drug resistance. Another antifolate combination, trimethoprim-sulfamethoxazole (TMP-SMZ), is widely used to prevent coinfections in patients infected with HIV, and it offers partial protection against malaria.

7. Artemisinins—Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used for various indications in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. WHO encourages availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. Of concern, delayed clearance of parasites and clinical failures have been seen after treatment with artesunate in parts of Southeast Asia, heralding the emergence of artemisinin resistance in this region.

Artemisinins play a vital role in the treatment of malaria, including multidrug-resistant *P. falciparum* malaria. Due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, leading to approved use only as initial therapy for severe malaria and in ACTs for uncomplicated malaria. The ACTs that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product. Another ACT, artesunate plus mefloquine is used mostly outside of Africa; its efficacy may be declining in parts of Asia. Dihydroartemisinin-piperaquine has shown excellent efficacy and is the first-line regimen in some countries in Southeast Asia, but recent studies have shown declining efficacy in Cambodia due to decreased activity of both components of the regimen. The newest approved ACT, artesunate-pyronaridine, is approved in some countries, but little used to date. Other ACTs not recommended by the WHO are available in some countries and have shown good efficacy in limited studies, including arterolane-piperaquine, artemisinin-piperaquine, and artemisinin-naphthoquine.

In studies of severe malaria, intramuscular artemether was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is

available, although parenteral quinine and quinidine remain acceptable alternatives. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins are very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Neutropenia, anemia, hemolysis, and elevated levels of liver enzymes have been noted rarely. Hemolysis may occur weeks after therapy with intravenous artesunate. Artemisinins are teratogenic in animals, but with good safety seen in humans, and the importance of effectively treating malaria during pregnancy, the WHO now recommends ACTs to treat uncomplicated malaria and intravenous artesunate to treat complicated malaria during all trimesters of pregnancy.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and the antifolate proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States (Table 35-4). It also appears to be active against other species of malaria parasites. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter durations of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.

Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs (Table 35-4). Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women (Table 35-4). The most common toxicities with clindamycin are gastrointestinal.

Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riamet). Oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it requires twice-daily dosing. Despite this limitation, due to its reliable efficacy against falciparum malaria, Coartem is the first-line therapy for malaria in many malarious countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not generally cause QT prolongation or the serious cardiac toxicity seen with halofantrine.

Prevention

Malaria is transmitted by night-biting anopheline mosquitoes. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, but effectiveness varies in part due to widespread insecticide resistance. Indoor spraying of insecticides is generally highly effective in Africa but limited by resource constraints.

Extensive efforts are underway to develop a malaria vaccine, but a vaccine offering a high level of protection is not anticipated in the near future. RTS,S vaccine, which is based on a sporozoite antigen, is the most advanced vaccine candidate. Multiple clinical trials showed about 25–50% protection against malaria in children in the year after immunization, but lower levels of protection in very young children, in areas of highest malaria exposure, and over longer periods of time. A new concept is seasonal malaria immunization, using short-acting vaccines during the high transmission season. Other approaches under study include vaccines containing erythrocytic, liver-stage,

and sexual-stage antigens, and use of radiation-attenuated or molecularly attenuated sporozoites.

When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov; 877-FYI-TRIP). Recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone for most other malarious areas, and doxycycline for areas with a high prevalence of multidrug-resistant falciparum malaria (principally parts of Southeast Asia) (Table 35–5). Recommendations should be checked regularly because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include ACTs, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However,

Table 35–5. Drugs for the prevention of malaria in travelers.¹

Drug	Use ²	Adult Dosage (all oral) ³
Chloroquine	Areas without resistant <i>Plasmodium falciparum</i>	500 mg weekly
Malarone	Areas with multidrug-resistant <i>P falciparum</i>	1 tablet (250-mg atovaquone/100-mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant <i>P falciparum</i>	250 mg weekly
Doxycycline	Areas with multidrug-resistant <i>P falciparum</i>	100 mg daily
Primaquine ⁴	Terminal prophylaxis of <i>Plasmodium vivax</i> and <i>Plasmodium ovale</i> infections; alternative for <i>P falciparum</i> prophylaxis	30-mg base daily for 14 days after travel

¹Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see Centers for Disease Control and Prevention's guidelines (phone: 800-CDC-INFO; <http://wwwnc.cdc.gov/travel/>). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.

²Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

³For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.

⁴Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.

intermittent preventive therapy, whereby at-risk populations (in particular pregnant women and children) receive antimalarial therapy at set intervals, is of increasing interest. This strategy may decrease the incidence of malaria while allowing antimalarial immunity to develop. During pregnancy, intermittent preventive therapy with sulfadoxine-pyrimethamine, provided once during both the second and third trimesters, has improved pregnancy outcomes. With increasing resistance the preventive efficacy of sulfadoxine-pyrimethamine is likely falling, and the long-acting ACT dihydroartemisinin-piperaquine is a promising replacement. In areas with seasonal malaria transmission and limited drug resistance, principally the Sahel subregion of West Africa, the policy is to administer amodiaquine and sulfadoxine-pyrimethamine to children monthly during the transmission season.

► Prognosis

When treated appropriately, uncomplicated malaria generally responds well, with resolution of fevers within 1–2 days and a mortality of about 0.1%. Severe malaria can commonly progress to death, but many children respond well to therapy. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Pregnant women are at particular risk during their first pregnancy. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

► When to Refer

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for falciparum malaria; referral should not delay initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

► When to Admit

- Admission for non-falciparum malaria is warranted only if specific problems that require hospital management are present.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

BABESIOSIS

ESSENTIALS OF DIAGNOSIS

- History of tick bite or exposure to ticks.
- Fever, flu-like symptoms, anemia.
- Intraerythrocytic parasites on Giemsa-stained blood smears.
- Positive serologic tests.

► General Considerations

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild mammals. Most babesiosis in the United States occurs in the coastal north-east, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. The incidence of the disease appears to be increasing in some areas. Babesiosis is caused by *Babesia divergens* in Europe and by *Babesia venatorum* in China. Babesiosis due to *Babesia duncani* and other *Babesia*-like organisms have been reported uncommonly from the western United States. Babesiosis can also be transmitted by blood transfusion, but blood supplies are not screened. A survey of a large set of blood samples from endemic

regions of the United States identified ~0.4% as potentially infectious for *B microti*.

Clinical Findings

A. Symptoms and Signs

Serosurveys suggest that asymptomatic infections are common in endemic areas. With *B microti* infections, symptoms appear 1 to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and acute kidney injury, with death rates over 40%.

B. Laboratory Findings

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis (Figure 35–6). These can be confused with malaria parasites, but the morphology is distinctive. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. Diagnosis can also be made by PCR, which is more sensitive than blood smear. An indirect immunofluorescent antibody test for *B microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months.

▲ **Figure 35–6.** Blood smear showing *Babesia* spp. rings with basophilic stippling. (From Dr. Mae Melvin, Public Health Image Library, CDC.)

Treatment

Most patients have a mild illness and recover without therapy. Standard therapy for mild to moderate disease is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily), which is equally effective and better tolerated than the alternative regimen, a 7-day course of quinine (650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). However, there is more experience using quinine plus clindamycin, and this regimen is recommended for severe disease. Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia greater than 10%.

TOXOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.

Primary infection

- ▶ Fever, malaise, headache, sore throat.
- ▶ Lymphadenopathy.
- ▶ Positive IgG and IgM serologic tests.

Congenital infection

- ▶ Follows acute infection of seronegative mothers and leads to CNS abnormalities and retinochoroiditis.

Infection in immunocompromised persons

- ▶ Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
- ▶ Positive IgG but negative IgM serologic tests.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of mammals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to

20–30% or less, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80%. In the United States, *T gondii* is estimated to infect 1.1 million persons each year, with resultant chorioretinitis developing in 21,000 and vision loss in 4800.

▶ Clinical Findings

A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. Primary infection in the immunocompetent person—

After ingestion, *T gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.

2. Congenital infection—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Retinochoroiditis and other sight-threatening eye lesions may develop. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life.

3. Retinochoroiditis—The most common late presentation of congenital toxoplasmosis is retinochoroiditis, which presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis is also seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. Disease in the immunocompromised person—Reactivated toxoplasmosis occurs in patients with AIDS, cancer,

or those given immunosuppressive drugs. In patients with advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or, more rarely, transmission of infection. Reactivation also can occur in those with hematologic malignancies or treated with immunosuppressive drugs. With primary or reactivated disease in those with immunodeficiency due to malignancy or immunosuppressive drugs, toxoplasmosis is similar to that in individuals with AIDS, but pneumonitis and myocarditis are more common.

B. Diagnostic Testing

1. Identification of parasites—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. Serologic diagnosis—Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection, and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. During pregnancy and in newborns—Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. Positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available

tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant, but persistence of positive IgG beyond 12 months of age is diagnostic of congenital infection. PCR of blood, CSF, or urine can also be helpful for early diagnosis of congenital disease.

4. In immunocompetent individuals—Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer greater than 1:64 are suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunodeficient individuals—A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculoma, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, fundoscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

► Treatment

A. Approach to Treatment

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month. Immunocompromised patients with active infection must be treated. For

those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

B. Medications

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200-mg loading dose, then 50–75 mg [1 mg/kg] orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative is clindamycin (600 mg orally four times daily) replacing sulfadiazine as the standard therapy regimen. Another alternative is replacement of sulfadiazine with TMP-SMZ. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for acute toxoplasmosis during pregnancy is spiramycin (1 g orally three times daily until delivery) to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

► Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. Irradiation, cooking to 66°C, or freezing to –20°C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For hematopoietic cell transplant recipients and advanced AIDS patients, chemoprophylaxis with TMP-SMZ (one double-strength tablet daily or two tablets three times weekly), used for protection against *Pneumocystis*, is effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

AMEBIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Organisms or antigen present in stools or abscess aspirate.
- ▶ Positive serologic tests with colitis or hepatic abscess, but these may represent prior infections.
- ▶ Mild to moderate colitis with recurrent diarrhea.
- ▶ Severe colitis including bloody diarrhea, fever, and abdominal pain, with potential progression to hemorrhage or perforation.
- ▶ Hepatic abscess with fever, hepatomegaly, and abdominal pain.

General Considerations

The *Entamoeba* complex contains three morphologically identical species: *Entamoeba dispar* and *Entamoeba moshkovskii*, which are avirulent, and *Entamoeba histolytica*, which may be an avirulent intestinal commensal or lead to serious disease. Disease follows penetration of the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery or extraintestinal disease, most commonly liver abscess.

E histolytica infections are present worldwide but are most prevalent in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Of the estimated 500 million persons worldwide infected with *Entamoeba*, most are infected with *E dispar* and an estimated 10% with *E histolytica*. The prevalence of *E moshkovskii* is unknown. Mortality from invasive *E histolytica* infections is estimated at 100,000 per year.

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and

use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

Clinical Findings

A. Symptoms and Signs

1. Intestinal amebiasis—In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea may begin within a week of infection, although an incubation period of 2–4 weeks is more common, with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days to weeks or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with more extensive diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

2. Extraintestinal amebiasis—The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

C. Diagnostic Testing

Diagnosis is by finding *E histolytica* or its antigen or by serologic tests. However, each method has limitations.

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. A commercially available stool antigen test (TechLab II) offers improved sensitivity (more than 90% for colitis); it requires fresh or frozen (not preserved) stool specimens. PCR-based tests are available but not used routinely. Colonoscopy of uncleaned bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling inflammatory bowel disease (Figure 35–7). Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

2. Hepatic abscess—Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The TechLab II antigen test can be used to test serum, with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative; the antigen test is positive in ~40% of cases. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage leading to peritonitis from amebas or other (pyogenic or echinococcal) organisms.

D. Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density

nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

▶ Treatment

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 35–6). Asymptomatic infection with *E dispar* does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but with negative serology *E dispar* colonization is likely, and treatment is not indicated. Colonization with *E histolytica* is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30-mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Treatment of intestinal amebiasis requires tinidazole (2 g orally once daily for 3 days for mild disease and 5 days for serious disease) or metronidazole (750 mg orally three times daily for 10 days) plus a luminal agent (Table 35–6). Tinidazole offers simpler dosing and fewer side effects than metronidazole whose side effects include transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is coingested. Metronidazole should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Alternatives for the treatment of intestinal amebiasis are tetracycline (250–500 mg orally four times daily for 10 days) plus chloroquine (500 mg orally daily for 7 days). Emetine or dehydroemetine, which are not available in the United States, can be given subcutaneously or intramuscularly in a dose of 1–1.5 mg/kg/day; the maximum daily dose is 90 mg for dehydroemetine and 65 mg for emetine). These agents are effective but cardiotoxic with a narrow therapeutic range and should be used only until severe disease is controlled. They cause nausea, vomiting, and pain at the injection site.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine,

▲ **Figure 35–7.** Gross pathology showing intestinal ulcers due to amebiasis. (From Dr. Mae Melvin, Public Health Image Library, CDC.)

Table 35–6. Treatment of amebiasis.¹

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate, ² 500 mg orally three times daily for 10 days or— Iodoquinol, 650 mg orally three times daily for 21 days or— Paromomycin, 10 mg/kg orally three times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or— Tinidazole, 2 g orally daily for 3 days plus— Luminal agent (see above)	Luminal agent (see above) plus either— Tetracycline, 250 mg orally three times daily for 10 days or— Erythromycin, 500 mg orally four times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or— Tinidazole, 2 g orally daily for 3 days plus— Luminal agent (see above)	Luminal agent (see above) plus either— Tetracycline, 250 mg orally three times daily for 10 days or— Dehydroemetine ² or emetine, ² 1 mg/kg subcutaneously or intramuscularly for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg orally three times daily (or 500 mg intravenously every 6 hours) for 10 days or— Tinidazole, 2 g orally daily for 3 days plus— Luminal agent (see above)	Dehydroemetine ² or emetine, ² 1 mg/kg subcutaneously or intramuscularly for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg orally twice daily for 2 days, then 500 mg daily for 21 days plus— Luminal agent (see above)

¹See text for additional details and cautions.²Not available in the United States.

emetine or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

► Prevention & Control

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of food; protection of food from fly contamination; hand washing; and, in endemic areas, avoidance of fruits and vegetables that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5-mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS

ESSENTIALS OF DIAGNOSIS

- Acute diarrhea, especially in children in developing countries.
- Outbreaks of diarrhea secondary to contaminated water or food.
- Prolonged diarrhea in immunocompromised persons.
- Diagnosis mostly by identifying organisms in specially stained stool specimens.

► General Considerations

The causes of coccidiosis are *Cryptosporidium* species (*C parvum*, *C hominis*, and others); *Isospora belli*; *Cyclospora cayetanensis*; and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon*

Gonzales ML et al. Antiamoebic drugs for treating amoebic colitis. Cochrane Database Syst Rev. 2009 Apr 15; (2): CD006085. [PMID: 19370624]

Wright SG. Protozoan infections of the gastrointestinal tract. Infect Dis Clin North Am. 2012 Jun;26(2):323–39. [PMID: 22632642]

bieneusi and *Encephalitozoon intestinalis*. These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler's diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

I belli and *C cayetanensis* appear to infect only humans. *C cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Cryptosporidiosis is a zoonosis (*C parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C hominus*. Cryptosporidia are highly infectious and readily transmitted in day care settings and households. They have caused large community outbreaks due to contaminated water supplies (causing ~400,000 illnesses in Milwaukee in 1993) and are the leading cause of recreational water-associated outbreaks of gastroenteritis. In the developing world cryptosporidiosis is a leading cause of childhood diarrhea. In a study of causes of moderate-to-severe diarrhea in Asia and Africa, *Cryptosporidium* was the second most commonly identified pathogen in children under 2 years of age.

Clinical Findings

A. Symptoms and Signs

1. Cryptosporidiosis—The incubation period appears to be 1–14 days. In developing countries, disease is primarily in children under 5 years of age, causing 5–10% of childhood diarrhea. Presenting symptoms include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts from 5 to 10 days. It is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection are also common.

Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common before the advent

of highly active antiretroviral therapy, particularly with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

2. Isosporiasis—The incubation period for *I belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

3. Cyclosporiasis—*C cayetanensis* oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

4. Sarcocystosis—*Sarcocystis* infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

5. Microsporidiosis—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with *E bieneusi* and *E intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen.

Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enterocytozoon*, *Encephalitozoon*, *Brachiola*, *Vittaforma*, *Pleistophora*, *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

B. Laboratory Findings

1. Cryptosporidiosis—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Various antigen detection methods, including immunofluorescence microscopy, ELISA, and immunochromatography, offer improved sensitivity and specificity, both over 90% with available assays, and these methods may be considered the optimal means of diagnosis. Molecular diagnostic panels that recognize *Cryptosporidium* and other enteropathogens in stool are available but expensive.

2. Isosporiasis—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

3. Cyclosporiasis—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

4. Sarcocystosis—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

5. Microsporidiosis—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

► Treatment

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require

treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. Cryptosporidiosis—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a nonabsorbed aminoglycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

2. Isosporiasis—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with TMP-SMZ (160 mg/800 mg orally two to four times daily for 10 days, with the higher dosage for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/day orally). Maintenance therapy with low-dose TMP-SMZ (160 mg/800 mg daily or three times per week) or Fansidar (1 tablet weekly) prevents relapse in those with persistent immunosuppression.

3. Cyclosporiasis—Cyclosporiasis is also treated with TMP-SMZ (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (160 mg/800 mg three times weekly) helps prevent relapse. For patients intolerant of TMP-SMZ, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than TMP-SMZ.

4. Sarcocystosis—For sarcocystosis, no specific treatment is established, but patients may respond to therapy with albendazole or TMP-SMZ.

5. Microsporidiosis—Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E. bienersi*, the most common microsporidian cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoplasty.

Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (hand washing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

GIARDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute diarrhea may be profuse and watery.
- ▶ Chronic diarrhea with greasy, malodorous stools.
- ▶ Abdominal cramps, distention, flatulence, and malaise.
- ▶ Cysts or trophozoites in stools.

General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *Giardia intestinalis* and *Giardia duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is 100,000 to 2.5 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to *Giardia*-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children's day care centers, and residential facilities, and may occur as a result of contamination of water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as ten cysts. After the cysts are ingested, trophozoites emerge in

the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernable infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is suspected, antigen assays are simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%). Molecular diagnostic panels that recognize *Giardia* and other enteropathogens in stool are available but expensive.

Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once). The drugs are not universally

effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Albendazole (400 mg orally once daily for 5 days) and nitazoxanide (500 mg orally twice daily for 3 days) both appear to have similar efficacy and fewer side effects compared with metronidazole, although data are limited, and a recent meta-analysis suggested superiority in efficacy of tinidazole over albendazole. Nitazoxanide is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against *Giardia* include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects, and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but unlike metronidazole, tinidazole, and furazolidone is safe in pregnancy. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection. With a suggestive presentation but negative diagnostic studies, an empiric course of treatment may be appropriate. Household or day care contacts with an index case should be tested and treated if infected.

► Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size less than 1 µm are adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

Escobedo AA et al. A meta-analysis of the efficacy of albendazole compared with tinidazole as treatments for *Giardia* infections in children. *Acta Trop*. 2016 Jan;153:120–7. [PMID: 26476393]

TRICHOMONIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ **Women:** copious vaginal discharge.
- ▶ **Men:** nongonococcal urethritis.
- ▶ Motile trichomonads on wet mounts.

► General Considerations

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common sexually transmitted diseases, causing vaginitis in women and

nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

► Clinical Findings

A. Symptoms and Signs

T vaginalis is often harbored asymptotically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

B. Diagnostic Testing

Diagnosis is traditionally made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginosis (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Newer point-of-care antigen detection and nucleic acid probe hybridization tests and nucleic acid amplification assays offer improved sensitivity compared to wet mount microscopy and excellent specificity.

► Treatment

The treatment of choice is tinidazole or metronidazole, each as a 2 g single oral dose. Tinidazole may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. A meta-analysis suggested that multiple dose regimens offer improved efficacy, although this is not standard. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, intravaginal paromomycin, or other experimental therapies (see Chapter 18).

HELMINTHIC INFECTIONS

TREMATODE (FLUKE) INFECTIONS

SCHISTOSOMIASIS (Bilharziasis)

ESSENTIALS OF DIAGNOSIS

- ▶ History of freshwater exposure in an endemic area.
- ▶ **Acute schistosomiasis:** fever, headache, myalgias, cough, urticaria, diarrhea, and eosinophilia.
- ▶ **Intestinal schistosomiasis:** abdominal pain, diarrhea, and hepatomegaly, progressing to anorexia, weight loss, and features of portal hypertension.
- ▶ **Urinary schistosomiasis:** hematuria and dysuria, progressing to hydronephrosis and urinary infections.
- ▶ **Diagnosis:** characteristic eggs in feces or urine; biopsy of rectal or bladder mucosa; positive serology.

General Considerations

Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by six species of trematode blood flukes. Five species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present in Africa, the Arabian peninsula, South America, and the Caribbean; *Schistosoma japonicum*, which is endemic in China and Southeast Asia; *Schistosoma mekongi*, which is endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum* and *Schistosoma guineensis*, which occur in parts of Africa. *Schistosoma haematobium* causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East. Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission significantly in many areas, but high level transmission remains common in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with freshwater containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomulae migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate, and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular

the liver. Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and inflammation, eventually leading to fibrosis. Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with freshwater contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

Clinical Findings

A. Symptoms and Signs

1. Cercarial dermatitis—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in nontropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer's itch).

2. Acute schistosomiasis (Katayama syndrome)

A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S. mansoni* or *S. japonicum*. Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. Chronic schistosomiasis—Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydronephrosis, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine. The most widely used stool test is the Kato-Katz technique. Quantitative tests that yield more than 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species, but cannot distinguish acute and

past infection. Sensitivity of the test is 99% for *S mansoni*, 95% for *S haematobium*, but less than 50% for *S japonicum*. Serology is of limited use in endemic settings, but can be helpful in travelers from nonendemic regions. Point-of-care assays to detect circulating schistosome antigens in serum and urine are also available; the most widely used tests target circulating anodic and cathodic antigens. Antigen tests have better sensitivity than stool smears, especially for *S mansoni*; sensitivity is lower for *S haematobium*. Molecular tests for schistosomiasis have been developed but are not routinely used for diagnosis. In acute schistosomiasis, leukocytosis and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue cannot distinguish past or active disease. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease.

▶ Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S mansoni*, *S haematobium*, *S intercalatum*, and *S guineensis* infections and a dose of 60 mg/kg (in two or three doses) for *S japonicum* and *S mekongi*. Cure rates are generally greater than 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and metrifonate for *S haematobium* infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections. The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

▶ Prevention

Travelers to endemic areas should avoid freshwater exposure. Vigorous towel drying after exposure may limit cercarial

penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent treatment to limit worm burdens.

LIVER, LUNG, & INTESTINAL FLUKES

FASCIOLIASIS

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe, and it has increasingly been recognized in travelers to these areas. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into freshwater, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver biochemical tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract. Serologic assays have sensitivity and specificity greater than 90%, but cannot distinguish between past and current infection. Antigen tests with excellent sensitivity and specificity are available in veterinary medicine and show promise for humans.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The treatment of choice is triclabendazole, which is also used in

veterinary medicine. It is not routinely available in the United States, but is available through the CDC under an investigational protocol. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. Of concern, resistance to triclabendazole has been widely reported in animal infections. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/day orally in three divided doses on alternate days for 10–15 days); this drug is no longer available in the United States. Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Other potential therapies are emetine and dehydroemetine, both widely used in the past but quite toxic, and nitazoxanide. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. An estimated 15 million people are infected (13 million in China); in some communities, prevalence can reach 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. The stool Kato-Katz test is widely used; performing repeated tests improves sensitivity. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic assays for clonorchiasis with excellent sensitivity are available but cannot distinguish between past and current infection. Molecular tests have been developed but are not widely used.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is

albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective. Tribendimidine, which is approved in China, has shown efficacy for clonorchiasis similar to that of praziquantel.

PARAGONIMIASIS

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*. *Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected; rare infections caused by *Paragonimus kellicotti* have occurred in North America. Eggs are released into freshwater, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity more than 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

INTESTINAL FLUKES

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in freshwater, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause

similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months, manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

CESTODE INFECTIONS

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to

cysticercosis, which is discussed under Invasive Cestode Infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B₁₂ deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, a repeat treatment after 1 week and screening after therapy to document cure are appropriate with heavy infections. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Craig P et al. Intestinal cestodes. *Curr Opin Infect Dis.* 2007 Oct; 20(5):524–32. [PMID: 17762788]

INVASIVE CESTODE INFECTIONS

1. Cysticercosis

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to *T solium* through fecal contamination of food.
- ▶ Focal CNS lesions; seizures, headache.
- ▶ Brain imaging shows cysts; positive serologic tests.

General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries. In Latin America, it is estimated that 0.5–1.5 million people suffer from epilepsy secondary to cysticercosis.

Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis. ELISAs and related immunoblot assays have excellent sensitivity and specificity, but sensitivity is lower with only single or calcified lesions.

C. Imaging

With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT.

Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis, but some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures. Overall, most authorities recommend treatment of active lesions, in particular lesions with a high likelihood of progression, such as intraventricular cysts. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. In addition, cysticidal therapy should be avoided if there is a high risk of hydrocephalus, as with subarachnoid involvement. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/day orally for 8 days) or praziquantel (50 mg/kg/day orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/day orally may improve outcomes. Combining albendazole plus praziquantel improved outcomes compared to albendazole alone in patients with multiple viable intraparenchymal cysts. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

Gripper LB et al. Neurocysticercosis infection and disease—a review. *Acta Trop.* 2017 Feb;166:218–24. [PMID: 27880878]

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to dogs or wild canines in an endemic area.
- ▶ Large cystic lesions, most commonly of the liver or lung.
- ▶ Positive serologic tests.

General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the Northern Hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

Clinical Findings

A. Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

Treatment

The treatment of cystic hydatid disease is with albendazole, often with cautious surgical resection of cysts. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/day orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/day orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicedal agent (95% ethanol, hypertonic saline, or 0.5% cetrimide) is injected, and the cyst is reaspirated after about 15 minutes. PAIR includes a small risk of anaphylaxis, which has been reported in about 2% of procedures, but death due to anaphylaxis has been rare. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

INTESTINAL NEMATODE (ROUNDWORM) INFECTIONS

ASCARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- ▶ Nonspecific abdominal symptoms.
- ▶ Eggs in stool; adult worms occasionally passed.

General Considerations

Ascaris lumbricoides is the most common of the intestinal helminths, causing about 800 million infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces, usually with the Kato-Katz technique. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400-mg oral dose), mebendazole (single 500-mg oral dose or 100 mg twice daily for [3 days), or pyrantel pamoate (single 11-mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. An alternative is ivermectin (single 200 mcg/kg oral dose). In endemic areas, reinfection after treatment is common. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about 500 million persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Eosinophilia is common. Treatment is typically with albendazole (400 mg/day orally) or mebendazole (200 mg/day orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. An alternative is ivermectin (200 mcg/kg orally once daily for 3 days). Oxantel pamoate (one dose of 15–30 mg/kg) has shown good efficacy in clearing infections, and randomized trials showed albendazole plus oxantel pamoate (31% cure; 96% egg reduction) to be superior to mebendazole, and albendazole plus oxantel pamoate (69% cure; 99% egg reduction) and albendazole plus ivermectin (28% cure; 95% egg reduction) to be superior to albendazole plus mebendazole. Oxantel pamoate has low efficacy against *Ascaris* and hookworm infection.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and lung symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Iron deficiency anemia.
- ▶ Characteristic eggs and occult blood in the stool.

General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 500 million, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

Treatment

Treatment is with albendazole (single 400-mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe

symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and lung symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Larvae detected in stool.
- ▶ Hyperinfection in the immunocompromised; larvae detected in sputum or other fluids.
- ▶ Eosinophilia.

General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation. The most dangerous manifestation of *S stercoralis* infection is the **hyperinfection syndrome**, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcoholism; or persons with AIDS. The risk seems greatest for those receiving corticosteroids.

Clinical Findings

A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With hyperinfection large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative (see below).

Treatment

Full eradication of *S. stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg/kg orally daily for 1–2 days). Less effective alternatives are albendazole (400 mg orally twice daily for 3 days) and thiabendazole (25 mg/kg orally twice daily for 3 days). For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated therapy (eg, monthly ivermectin) may be required.

ENTEROBIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Nocturnal perianal pruritus.
- ▶ Identification of eggs or adult worms on perianal skin or in stool.

General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-aged children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time, they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short life span of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

▶ Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard hand washing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

[PMID: 25589326]

INVASIVE NEMATODE (ROUNDWORM) INFECTIONS

TRICHINOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Ingestion of inadequately cooked pork or game.
- ▶ Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- ▶ Eosinophilia and elevated serum muscle enzymes.

▶ General Considerations

Trichinosis (or trichinellosis) is caused worldwide by *Trichinella spiralis* and related *Trichinella* species. The disease is spread by ingestion of undercooked meat, most

commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, *Trichinella* larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks, with estimates of ~10,000 cases annually. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 20 infections are reported annually, mostly from ingesting wild game.

▶ Clinical Findings

A. Symptoms and Signs

Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

B. Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase). The erythrocyte sedimentation rate is usually normal, which may help distinguish trichinosis from autoimmune myopathies. A commercial ELISA assay is available in the United States. Serologic tests become positive 2 or more weeks after infection, but cross-reactivity can be seen with other parasites. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify *Trichinella* larvae. For maximal yield, biopsy material should be examined histologically, and a portion enzymatically digested to release larvae, but evaluation before 3 weeks after infection may not show muscle larvae. Serum and muscle biopsy analysis are available from the CDC.

Treatment

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Infection is prevented by cooking to a temperature of at least 71°C for at least 1 minute. Irradiation of meat is also effective in eliminating *Trichinella* larvae, but freezing is not reliable.

Gottstein B et al. Epidemiology, diagnosis, treatment, and control of trichinellosis. Clin Microbiol Rev. 2009 Jan;22(1):127–45. [PMID: 19136437]

TOXOCARIASIS

General Considerations

The dog roundworm *Toxocara canis*, the cat roundworm *Toxocara cati*, and less commonly other helminths may cause visceral larva migrans. *T canis* is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. Infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, typically with similar, but more severe manifestations than *T canis*.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an ELISA against a group of excreted antigens has shown good sensitivity and specificity. Molecular assays can identify specific pathogens. Most patients recover without specific therapy, although symptoms may persist for months.

Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg orally twice daily for 5 days), mebendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

Ma G et al. Human toxocariasis. Lancet Infect Dis. 2018 Jan;18(1):e14–24. [PMID: 28781085]

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the nonhuman parasites cannot complete their life cycles, so only cause cutaneous disease.

Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 35–8). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment.

▲ **Figure 35–8.** Cutaneous larva migrans on the foot. (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.

FILARIASIS

LYMPHATIC FILIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic attacks of lymphangitis, lymphadenitis, and fever.
- ▶ Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- ▶ Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

General Considerations

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including sub-Saharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia. *Mansonnella* are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilariaemia peaks during daylight hours).

Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing,

▲ **Figure 35–9.** Elephantiasis of legs due to filariasis. (Public Health Image Library, CDC.)

mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Figure 35–9); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W bancrofti* or *B malayi* infection, but typically without microfilariaemia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. *Mansonnella* can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but during daylight hours in the South Pacific. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Serologic tests may be helpful but cannot distinguish past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available for detection of *W bancrofti*. These can be considered the diagnostic tests of choice and are increasingly used to guide control programs. However, cross-reactivity with *Loa loa* infections has been described. Due to potential severe toxicity, caution is appropriate before treatment with ivermectin for positive *W bancrofti* antigen tests in areas also endemic for *L loa* infection. Multiple molecular tests, including field-friendly LAMP assays, have been developed. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaremia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds.

► Treatment & Control

A. Drug Treatment

Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. A single dose of all three drugs offered superior clearance of parasites compared to diethylcarbamazine plus albendazole. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management

of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes, but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/day orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Doxycycline was also effective at controlling *Mansonella perstans* infection, which does not respond well to standard antifilarial drugs. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin; in some circumstances, more frequent dosing offers improved control.

Thomsen EK et al. Efficacy, safety, and pharmacokinetics of coadministered diethylcarbamazine, albendazole, and ivermectin for treatment of Bancroftian Filariasis. Clin Infect Dis. 2016 Feb 1;62(3):334–41. [PMID: 26486704]

ONCHOCERCIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Conjunctivitis progressing to blindness.
- ▶ Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- ▶ Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

► General Considerations

Onchocerciasis, or river blindness, is caused by *Onchocerca volvulus*. An estimated 37 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in sub-Saharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simuliid flies (black-flies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

Clinical Findings

A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

B. Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzotti test can be used; exacerbation of skin rash and pruritus after a 50-mg dose of diethylcarbamazine is highly suggestive of the diagnosis. This test should only be used after other tests are negative, since treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is also available. Eosinophilia is a common, but inconsistent finding. Antigen and antibody detection tests are under study.

Treatment & Control

The treatment of choice is ivermectin, which kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected life span of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 4–6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline shows promise as a first-line agent to treat onchocerciasis because of its improved activity against adult worms compared to other agents and limited toxicity due to the slow action of the drug.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

Debrah AY et al. Doxycycline leads to sterility and enhanced killing of female *Onchocerca volvulus* worms in an area with persistent microfilaridemia after repeated ivermectin treatment: a randomized, placebo-controlled, double-blind trial. Clin Infect Dis. 2015 Aug 15;61(4):517–26. [PMID: 25948064]

LOIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Subcutaneous swellings; adult worms migrating across the eye.
- ▶ Encephalitis, which may be brought on by treatment.
- ▶ Microfilariae in the blood.

General Considerations

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term “eye worm”). Adults can live for up to 17 years.

Clinical Findings

A. Symptoms and Signs

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings) develop in symptomatic persons. The swellings are nonerythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high-level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

B. Laboratory Findings

The diagnosis is established by identifying microfilariae in blood. Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test

results. Molecular methods, including field-friendly LAMP assays, are available to rule out loiasis before administration of ivermectin for the control of other filarial infections.

Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment is with 8–10 mg/kg/day orally for 21 days; repeat courses may be needed. Mild side effects are common, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, entails a higher risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin. Doxycycline is not effective for loiasis.

Kamgno J et al. Effect of two or six doses 800 mg of albendazole every two months on *Loa loa* microfilaremia: a double blind, randomized, placebo-controlled trial. *PLoS Negl Trop Dis*. 2016 Mar 11;10(3):e0004492. [PMID: 26967331]

Mycotic Infections

Samuel A. Shelburne III, MD, PhD

Richard J. Hamill, MD

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Common normal flora but opportunistic pathogen.
- ▶ Mucosal disease, particularly vaginitis and esophagitis.
- ▶ Risk factors for fungemia: neutropenia, intravenous catheter, abdominal surgery, total parenteral nutrition, kidney disease, broad-spectrum antibiotics.

General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, kidney disease, and the presence of intravascular catheters (especially when providing total parenteral nutrition). Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

Clinical Findings

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum

antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization. However, symptoms and signs of true *Candida* urinary tract infections are indistinguishable from bacterial urinary tract infections and can include urgency, hesitancy, fever, chills, or flank pain.

C. Invasive Candidiasis

Invasive candidiasis can be (1) candidemia without deep-seated infection; (2) candidemia with deep-seated infection (typically eyes, kidney, or abdomen); and (3) deep-seated candidiasis in the absence of bloodstream infection. Varying ratios of these clinical entities depends on the predominating risk factors for affecting patients (ie, neutropenia, dialysis, postsurgical). The clinical presentation of candidemia varies from minimal fever to septic shock that can resemble a severe bacterial infection. The diagnosis of invasive *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in invasive infection. Consecutively positive (1,3)-beta-D-glucan results may be used to guide empiric therapy in high-risk patients even in the absence of positive blood cultures.

Hepatosplenic candidiasis can occur following prolonged neutropenia in patients with underlying hematologic cancers, but this entity is less common in the era of widespread antifungal prophylaxis. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection that is most frequently associated with exposure to a health care setting.

Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement.

► Treatment

A. Mucosal Candidiasis

Therapy of **esophageal candidiasis** depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/day (or itraconazole solution, 10 mg/mL, 200 mg/day), for 10–14 days usually suffices. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/day; intravenous caspofungin, 50 mg/day; intravenous anidulafungin, 100 mg on day 1, then 50 mg/day; or intravenous micafungin, 150 mg/day. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Various topical azole preparations (eg, clotrimazole, 100-mg vaginal tablet for 7 days, or miconazole, 200-mg vaginal suppository for 3 days) are effective against **vulvovaginal candidiasis**. One 150-mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of invasive infection. When symptomatic funguria persists, oral fluconazole, 200 mg/day for 7–14 days, can be used.

C. Invasive Candidiasis

The 2016 guidelines for management of candidiasis recommend an echinocandin such as caspofungin (loading dose of 70 mg intravenously once, then 50 mg intravenously daily), micafungin (100 mg intravenously daily), or anidulafungin (loading dose of 200 mg intravenously once, then 100 mg intravenously daily). Fluconazole (loading dose of 800 mg [12 mg/kg] intravenously, then 400 mg [6 mg/kg] intravenously daily) is an acceptable alternative for less critically ill patients without recent azole exposure. Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. A dilated fundoscopic examination is recommended for patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Once patients have become clinically stable, parenteral therapy can be

discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment for isolates known to be or likely to be susceptible to fluconazole. Removal or exchange of intravascular catheters is generally recommended for patients with candidemia in whom the catheter is the suspected source of infection.

Non-*albicans* species of *Candida* account for over 50% of clinical bloodstream isolates and often have resistance patterns that are different from *C. albicans*. An echinocandin is recommended for treatment of *Candida glabrata* infection with a transition to oral fluconazole or voriconazole reserved for patients whose isolates are known to be susceptible to these agents. *C. glabrata* that is resistant to azoles and echinocandins is being increasingly reported. Similarly, *Candida krusei* is generally fluconazole-resistant and so should be treated with an alternative agent, such as echinocandin or voriconazole. Fluconazole may be optimal for *Candida parapsilosis* due to possible echinocandin resistance in such isolates. Cases of health care–associated infections due to multidrug-resistant *Candida auris* have been described from several countries, including the United States, with most cases having been treated with echinocandins.

Although the isolation of *Candida* species from mucosal sites raises the possibility of invasive candidiasis, randomized trials of empiric antifungal agents in such situations have not shown clear clinical benefit. Hepatosplenic candidiasis generally requires treatment for several months until lesion resolution.

D. Candidal Endocarditis

Best results are achieved with a combination of medical and surgical therapy. Lipid formulation amphotericin B (3–5 mg/kg/day) or high-dose echinocandin (caspofungin 150 mg/day, micafungin 150 mg/day, or anidulafungin 200 mg/day) is recommended as initial therapy. Step-down or long-term suppressive therapy for nonsurgical candidates may be done with fluconazole at 6–12 mg/kg/day for susceptible organisms.

In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections, although the effect on mortality and the preferred agent remain debated.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to bird and bat droppings; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- ▶ Most patients asymptomatic; respiratory illness most common clinical problem.
- ▶ Disseminated disease common in AIDS or other immunosuppressed states; poor prognosis.
- ▶ Blood and bone marrow cultures as well as urine polysaccharide antigen, useful in diagnosis of disseminated disease.

General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and Southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) **Acute pulmonary histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. Clinical manifestations can vary from a mild influenza-like illness to severe pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is commonly seen in patients with underlying HIV infection (with CD4 cell counts usually less than 100 cells/mCL) or other conditions of impaired cellular immunity. Disseminated histoplasmosis has also been reported in patients from endemic areas taking tumor necrosis factor (TNF)-blocking agents. It is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present.

The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands; this results in adrenal insufficiency in about 50% of patients. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Chronic pulmonary histoplasmosis** is usually seen in older patients who have underlying chronic lung disease. Chest radiographs show various lesions including apical cavities, infiltrates, and nodules. (4) **Complications of pulmonary histoplasmosis** include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to *Histoplasma* infection results in compromise of pulmonary vascular structures.

B. Laboratory Findings

Most patients with chronic pulmonary disease show anemia of chronic disease. Bone marrow involvement with pancytopenia may be prominent in disseminated forms. Marked lactate dehydrogenase (LD) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase.

With pulmonary involvement, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of a first morning urine and serum polysaccharide antigen assays has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time, but may take several weeks for growth. The urine antigen assay has a sensitivity of greater than 90% for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy.

Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/day orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Therapeutic drug monitoring of itraconazole levels should be performed to assess adequacy of drug absorption. Duration of therapy ranges from weeks to several months depending on the severity of illness. Intravenous amphotericin B formulations are used in patients with more severe illness such as meningitis, with guidelines favoring the use of liposomal or lipid complex amphotericin formulations at a dose of 3 mg/kg/day over amphotericin B deoxycholate. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200 mg/day orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy. Criteria for discontinuing secondary prophylaxis include 1 year of successful antifungal therapy and a CD4 cell count of greater

than 150 cells/mcL and 6 months or more of antiretroviral treatment (ART). There is no clear evidence that antifungal or anti-inflammatory agents are of benefit for patients with granulomatous mediastinitis or fibrosing mediastinitis although oral itraconazole is often used. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Influenza-like illness: malaise, fever, backache, headache, and cough.
- ▶ Erythema nodosum common with acute infection.
- ▶ Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- ▶ Chest radiograph findings vary from pneumonitis to cavitation.
- ▶ Serologic tests useful; large spherules containing endospores demonstrable in sputum or tissues.

General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area. Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C. posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America. Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.

Clinical Findings

A. Symptoms and Signs

Symptoms of **primary coccidioidomycosis** occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized, etiology of community-acquired pneumonia in endemic areas.

Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In **primary coccidioidomycosis**, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test and enzyme-linked immunosorbent assay (ELISA) detect IgM antibodies and are both useful for diagnosis early in the disease process. A persistent rising IgG complement fixation titer (1:16 or more) is suggestive of disseminated disease; in addition, immunodiffusion complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases; *Coccidioides* antigen or (1,3)-beta-D-glucan testing may augment (not replace) CSF antibody testing. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens of soft tissues and bone; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive.

C. Imaging

Radiographic findings vary, but patchy, nodular, and lobar upper lobe pulmonary infiltrates are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests

dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft tissue collections.

► Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter 30). Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–1200 mg/day), although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/day is used initially by some clinicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/day intravenously, is generally given concurrently with intrathecal therapy, but is not sufficient alone for the treatment of meningeal disease. Once the patient is clinically stable, oral therapy with an azole, usually with fluconazole (400 mg daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Itraconazole, 400 mg orally daily divided into two doses, or fluconazole, 200–400 mg, or higher, orally once or twice daily should be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. Response to therapy should be monitored by following the clinical response and progressive decrease in serum complement fixation titers.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone, and complicated pulmonary disease (eg, rupture of coccidioidal cavity).

► Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis with stroke and hydrocephalus that may require shunting. There may be a benefit from short-term systemic corticosteroids following cerebrovascular events associated with coccidioides meningitis. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (*Pneumocystis jirovecii* Pneumonia)

ESSENTIALS OF DIAGNOSIS

- Fever, dyspnea, dry cough, hypoxia.
- Often only slight lung physical findings.
- Chest radiograph: diffuse interstitial disease or normal.
- *P jirovecii* in sputum, bronchoalveolar lavage fluid, or lung tissue; PCR of bronchoalveolar lavage; (1,3)-beta-D-glucan in blood.

► General Considerations

Pneumocystis jirovecii, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P jirovecii* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. Accumulating evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. De novo infection and reactivation of latent disease likely contribute to the mechanism of acute disease in older children and adults.

The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immunity. Cases occur commonly in patients with cancer or severe malnutrition and debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer and, most frequently, in patients with AIDS (Chapter 31).

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts less than 200/mcL. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

► Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is typically abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with

Gabe LM et al. Diagnosis and management of coccidioidomycosis. Clin Chest Med. 2017 Sep;38(3):417–33. [PMID: 28797486]
Galgiani JN et al. Executive summary: 2016 Infectious Diseases Society of America (IDSA) clinical practice guideline for the treatment of coccidioidomycosis. Clin Infect Dis. 2016 Sep 15;63(6):717–22. [PMID: 27559032]

spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jirovecii* pneumonia, helping distinguish it from other causes of pneumonia.

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients exercise before samples are drawn. Serologic tests are not helpful in diagnosis; measurement of serum (1,3)-beta-D-glucan levels has good sensitivity, although specificity is compromised by being positive in other fungal infections. The organism cannot be cultured, and definitive diagnosis depends on morphologic demonstration of the organisms in respiratory specimens using specific stains. Polymerase chain reaction (PCR) of bronchoalveolar lavage is overly sensitive in that the test can be positive in colonized, noninfected persons but quantitative values may help with identifying infected patients, although precise cutoffs have not been established. A negative PCR from bronchoalveolar lavage rules out disease. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia.

Treatment

(See Table 31–6.) It is appropriate to start empiric therapy for *P jirovecii* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The best-studied second-line option is a combination of primaquine and clindamycin, although dapsone/trimethoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected medication for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the

presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see below). Some clinicians prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage of TMP/SMZ is 15–20 mg/kg/day (based on trimethoprim component) given orally or intravenously daily in three or four divided doses for 14–21 days. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

B. Primaquine/Clindamycin

A meta-analysis suggested that primaquine, 15–30 mg/day, plus clindamycin, 600 mg three times daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

C. Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This medication is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/day for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur.

D. Atovaquone

Atovaquone is FDA approved for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Atovaquone should be administered with a fatty meal.

E. Other Medications

Trimethoprim, 15 mg/kg/day in three divided doses daily, plus dapsone, 100 mg/day, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when Pao₂ on admission is less than 70 mm Hg or oxygen saturation is less than 90%) in conjunction with antimicrobials. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed. The role of prednisone in non-AIDS patients is unclear, especially in patients in whom symptoms develop following tapering doses of corticosteroids.

Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts less than 200 cells/mcL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–5). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients, although the clinical characteristics of persons with these conditions who would benefit from *Pneumocystis* prophylaxis have not been clearly defined. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintained a CD4 count of greater than 200 cells/mcL.

Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

Fauchier T et al. Detection of *Pneumocystis jirovecii* by quantitative PCR to differentiate colonization and pneumonia in immunocompromised HIV-positive and HIV-negative patients. *J Clin Microbiol.* 2016 Jun;54(6):1487–95. [PMID: 27008872]

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of fungal meningitis.
- ▶ Predisposing factors: chemotherapy for hematologic malignancies, Hodgkin lymphoma, corticosteroid therapy, transplant recipients, TNF inhibitor therapy, HIV infection.
- ▶ Headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- ▶ Demonstration of capsular polysaccharide antigen or positive culture in cerebrospinal fluid is diagnostic.

General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been

found worldwide in soil and on dried pigeon dung. *C. gattii* is a closely related species that also causes disease in humans, although *C. gattii* may affect more ostensibly immunocompetent persons. It is a major cause of cryptococcosis in the Pacific northwestern region of the United States and may result in more severe disease than *C. neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic malignancies under treatment, Hodgkin lymphoma, long-term corticosteroid therapy, solid-organ transplant, TNF-inhibitor therapy, or HIV infection.

Clinical Findings

A. Symptoms and Signs

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. *C. gattii* infection frequently presents with respiratory symptoms along with neurologic signs caused by space-occupying lesions in the central nervous system. Primary *C. neoformans* infection of the skin may mimic bacterial cellulitis, especially in persons receiving immunosuppressive therapy such as corticosteroids. Paradoxical clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

B. Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungi. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas. Antigen testing by lateral flow assay appears to have improved sensitivity and specificity

over the conventional latex agglutination test and can provide more rapid diagnostic results.

Treatment

Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Liposomal amphotericin B, 3–4 mg/kg/day intravenously for 14 days is the preferred agent for induction therapy, followed by an additional 8 weeks of fluconazole, 400 mg/day orally. This regimen has been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/day divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in kidney function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. Corticosteroids should not be used. *Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality.* The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and Mini-Mental State Examination scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is higher. Therapy is generally continued until cerebrospinal fluid cultures become negative. Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/day orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count greater than 100–200 cells/mL for at least 6 months). Among clinicians treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; published guidelines suggest this as an option.

Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in

either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of non-candidal invasive fungal infection in transplant recipients and in patients with hematologic malignancies.
- ▶ Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- ▶ Pulmonary, sinus, and central nervous system are most common disease sites.
- ▶ Detection of galactomannan by ELISA or PCR in serum or other body fluids is useful for early diagnosis and treatment.

General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

Clinical Findings

A. Symptoms and Signs

1. Allergic forms of aspergillosis—Allergic bronchopulmonary aspergillosis (ABPA) occurs in patients with pre-existing asthma or cystic fibrosis who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. Allergic aspergillus sinusitis produces a chronic sinus inflammation characterized by eosinophilic mucus and noninvasive hyphal elements.

2. Chronic aspergillosis—Chronic pulmonary aspergillosis produces a spectrum of disease that usually occurs when there is preexisting lung damage but not significant immunocompromise. Disease manifestations range from aspergillomas that develop in a lung cavity to chronic fibrosing pulmonary aspergillosis in which the majority of lung tissue is replaced with fibrosis. Long-standing (longer than 3 months) pulmonary and systemic symptoms such as cough, shortness of breath, weight loss, and malaise are common.

3. Invasive aspergillosis—Invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, such as those who have undergone hematopoietic stem cell transplantation or have prolonged, severe neutropenia, but

it can occur among critically ill immunocompetent patients as well. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential.

B. Laboratory Findings

There is eosinophilia, high levels of total IgE, and IgE and IgG specific for *Aspergillus* in the blood of patients with ABPA.

Blood cultures have very low yield in any form of aspergillosis. Detection of galactomannan by ELISA or *Aspergillus* DNA by PCR, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done and usefulness is decreased in patients receiving anti-mold prophylaxis (ie, voriconazole or posaconazole). Galactomannan levels and *Aspergillus* DNA PCR can be tested in serum or in bronchoalveolar lavage fluid, which may be more sensitive than serum. Higher galactomannan levels are correlated with increased mortality, and failure of galactomannan levels to fall in response to therapy portends a worse outcome. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign,” which is a zone of diminution of ground glass around a consolidation).

► Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include voriconazole and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

► Treatment

1. Allergic forms of aspergillosis—For acute exacerbations of ABPA, oral prednisone is begun at a dose of 0.5 mg/kg/day and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole is increasingly being used. Itraconazole is the best studied agent for the treatment of allergic aspergillus sinusitis with topical corticosteroids being the cornerstone of therapy.

2. Chronic aspergillosis—The most effective therapy for symptomatic aspergilloma remains surgical resection.

Other forms of chronic aspergillosis are generally treated with at least 4–6 months of oral triazole therapy (itraconazole 200 mg twice daily, voriconazole 200 mg twice daily, or posaconazole 300 mg daily).

3. Invasive aspergillosis—The 2016 Infectious Diseases Society of America guidelines consider voriconazole (6 mg/kg intravenously twice on day 1 and then 4 mg/kg every 12 hours thereafter) as optimal therapy for invasive aspergillosis. A randomized controlled trial did not find an overall benefit with the addition of anidulafungin (200 mg on day 1 and then 100 mg daily) to voriconazole, but among patients in whom galactomannan was detected, those who received combination therapy had better outcomes. Isavuconazole (372 mg of prodrug on days 1 and 2 and then 372 mg once daily) was equivalent to voriconazole. Alternatives include a lipid formulation of amphotericin B (3–5 mg/kg/day), caspofungin (70 mg intravenously on day 1 and then 50 mg/day thereafter), and posaconazole oral tablets (300 mg twice daily on day 1 and then 300 mg daily thereafter). Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy. Therapeutic drug monitoring should be considered for both voriconazole and posaconazole given variations in metabolism and absorption.

Surgical debridement is generally done for sinusitis, and can be useful for focal pulmonary lesions, especially for treatment of life-threatening hemoptysis and infections recalcitrant to medical therapy. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains high, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of non-*Aspergillus* invasive mold infection.
- **Predisposing factors:** poorly controlled diabetes, leukemia, transplant recipient, wound contamination by soil.
- Pulmonary, rhinocerebral, and skin are most common disease sites.
- Rapidly fatal without multidisciplinary interventions.

General Considerations

The term “mucormycosis” is applied to opportunistic infections caused by members of the genera *Rhizopus*, *Mucor*, *Lichtheimia* (formerly *Absidia*), and *Cunninghamella*. Predisposing conditions include hematologic malignancy, stem cell transplantation, solid organ transplantation, diabetic ketoacidosis, chronic kidney disease, and treatment with desferoxamine, corticosteroids or cytotoxic drugs.

Clinical Findings

Invasive disease of the sinuses, orbits, and the lungs may occur. Necrosis is common due to hyphal tissue invasion that may manifest as ulceration of the hard palate or nasal palate or hemoptysis. Widely disseminated disease can occur. No serologic or laboratory findings assist with diagnosis, and blood cultures are unhelpful. A reverse “halo sign” (focal area of ground glass diminution surrounded by a ring of consolidation) may be seen on chest CT. Biopsy of involved tissue remains the cornerstone of diagnosis, although cultures are frequently negative. The organisms appear in tissues as broad, branching nonseptate hyphae.

Treatment

Optimal therapy of mucormycosis involves reversal of predisposing conditions (if possible), surgical debridement, and prompt antifungal therapy. A prolonged course of a lipid preparation of intravenous liposomal amphotericin B (5 mg/kg with higher doses possibly given for CNS disease) should be started early. Depending on in vitro susceptibility, posaconazole 300 mg/day orally can be used after disease has been stabilized. Combination therapy with amphotericin and posaconazole is not proven, but is commonly used because of the poor response to monotherapy. Isavuconazole has been shown to have some clinical activity. Other azoles are not effective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for rhino-orbital mucormycosis in diabetic patients. Despite favorable animal studies, a pilot study in humans incorporating adjunctive iron chelation therapy with deferasirox demonstrated a higher mortality rate than antifungal therapy alone. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis remains guarded.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities outdoors and in a geographically limited area of the south central and

midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Chronic pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal lobar consolidation or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a thick-walled cell 5–20 μm in diameter that may have a single broad-based bud. It grows readily on culture. A urinary antigen test is available, but it has considerable cross reactivity with other dimorphic fungi; it may be useful in monitoring disease resolution or progression. A serum enzyme immunoassay based on the surface protein BAD-1 has much better sensitivity and specificity than the urinary antigen test, but it is not yet commercially available.

Itraconazole, 200–400 mg/day orally for at least 6–12 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Liposomal amphotericin B, 3–5 mg/kg/day intravenously, is given initially for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

McBride JA et al. Clinical manifestations and treatment of blastomycosis. Clin Chest Med. 2017 Sep;38(3):435–49. [PMID: 28797487]

PARACOCIDIOMYCOSIS (South American Blastomycosis)

Paracoccidioides brasiliensis and *Paracoccidioides lutzii* infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. An acute form of the disease affects predominately younger patients and involves the mononuclear phagocytic system, resulting in progressive lymphadenopathy. A more chronic form affects mostly adult men and involves the lung, skin, mucous membranes, and lymph nodes. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Lymph

node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. HIV-infected patients with paracoccidioidomycosis are more likely to have extrapulmonary dissemination and a more rapid clinical disease course.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in more than 80% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. TMP-SMZ (480 mg/1200 mg) twice daily orally is equally effective and less costly but associated with more adverse effects and longer time to clinical cure. Amphotericin B, 0.7–1.0 mg/kg/day intravenously, is the medication of choice for severe and life-threatening infection.

Nery AF et al. Therapeutic response in adult patients with non-severe chronic paracoccidioidomycosis treated with sulfamethoxazole-trimethoprim: a retrospective study. *Am J Trop Med Hyg.* 2017 Aug;97(2):556–62. [PMID: 28722596]
Shikanai-Yasuda MA et al. Brazilian guidelines for the clinical management of paracoccidioidomycosis. *Rev Soc Bras Med Trop.* 2017 Sep–Oct;50(5):715–40. [PMID: 28746570]

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by organisms of the *Sporothrix schenckii* complex. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, lymphocutaneous spread along the lymphatics draining this area occurs, which may result in ulceration. Cavitory pulmonary disease occurs in individuals with underlying chronic lung disease.

Disseminated sporotrichosis is rare in immunocompetent persons but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with cellular immunodeficiencies, including AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. The usefulness of serologic tests is limited, but may be helpful in diagnosing disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 0.7–1.0 mg/kg/day, or a lipid amphotericin B preparation, 3–5 mg/kg/day are used for severe systemic infection. Surgery may be indicated for complicated

pulmonary cavitory disease, and joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Orofino-Costa R et al. Sporotrichosis: an update on epidemiology, etiopathogenesis, laboratory and clinical therapeutics. *An Bras Dermatol.* 2017 Sep–Oct;92(5):606–20. [PMID: 29166494]

MYCETOMA (Eumycetoma & Actinomycetoma)

Mycetoma is a chronic local, slowly progressive destructive infection that usually involves the foot; it begins in subcutaneous tissues, frequently after implantation trauma, and then spreads to contiguous structures with sinus tracts and extruding grains. Eumycetoma (also known as maduromycosis) is the term used to describe mycetoma caused by true fungi. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Causative species can often be suggested by the color of the characteristic grains and hyphal size within the infected tissues but definitive diagnosis requires culture.

The prognosis for eumycetoma is poor, though surgical debridement along with prolonged oral itraconazole therapy, 200 mg twice daily, or combination therapy including itraconazole and terbinafine may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

Relhan V et al. Mycetoma: an update. *Indian J Dermatol.* 2017 Jul–Aug;62(4):332–40. [PMID: 28794542]
van de Sande W et al. Closing the mycetoma knowledge gap. *Med Mycol.* 2018 Apr 1;56(suppl_1):153–64. [PMID: 28992217]

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are now significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons in whom multiple, painful skin lesions develop; blood cultures are often positive. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections

are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole). Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts.

Skiada A et al. Rare fungal infectious agents: a lurking enemy. *F1000Res*. 2017 Oct 31;6:1917. [PMID: 29152230]

Molds are commonly present in homes, particularly in the presence of moisture, and patients will commonly seek assessment for whether their illness is due to molds. Invasive disease due to environmental fungi can occur in the immunocompromised patient (eg, see section on Invasive Aspergillosis), but there are no data that mold exposure can induce immune dysfunction. Similarly, the concept of toxic-mold syndrome or cognitive impairment due to inhalation of mycotoxins has not been validated despite scrutiny by expert panels. Allergic symptoms (eg, asthma, hypersensitivity pneumonitis) can be worsened by environmental mold exposure, and reduction of household mold in such patients may lead to clinical improvement. The presence of mold in the household is typically easily discernable with visual inspection or detection by odor; if present, predisposing conditions should be corrected by individuals experienced in mold remediation.

Borchers AT et al. Mold and human health: a reality check. *Clin Rev Allerg Immunol*. 2017 Jun;52(3):305–22. [PMID: 28299723]

HOUSEHOLD MOLDS

ESSENTIALS OF DIAGNOSIS

- ▶ Molds are very common indoors where moisture exists in enclosed spaces.
- ▶ Most common indoor molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*.
- ▶ People most at risk for health problems include those with allergies, asthma, and underlying immunocompromising conditions.

ANTIFUNGAL THERAPY

Table 36–1 summarizes the major properties of currently available antifungal agents. Two different lipid-based amphotericin B formulations are used to treat systemic invasive fungal infections. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are approved for use. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive *Candida* infections, although resistance is beginning to emerge clinically; *C glabrata* in particular has shown resistance to this class of antifungals.

Table 36–1. Agents for systemic mycoses (listed in alphabetical order).

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Amphotericin B	0.3–1.5 mg/kg/day intravenously	No	Poor	Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular acidosis, anemia	All major pathogens except <i>Scedosporium</i>
Amphotericin B lipid complex	5 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above
Amphotericin B, liposomal	3–6 mg/kg/day intravenously	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above
Anidulafungin	100-mg intravenous loading dose, followed by 50 mg/day intravenously in one dose	< 1%	Poor	Diarrhea, hepatic enzyme elevations, histamine-mediated reactions	Mucosal and invasive candidiasis

(continued)

Table 36–1. Agents for systemic mycoses. (continued)

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Caspofungin acetate	70-mg intravenous loading dose, followed by 50 mg/day intravenously in one dose	< 50% ¹	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia
Fluconazole	100–800 mg/day in one or two doses intravenously or orally	Yes	Yes	Nausea, rash, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis
Flucytosine (5-FC)	100–150 mg/kg/day orally in four divided doses	Yes	Yes	Leukopenia, ² rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis, ³ candidiasis, ³ chromomycosis
Isavuconazole	200 mg/day orally or intravenously once daily	No	Low in CSF, high in brain	Nausea, diarrhea, upper abdominal pain, dizziness	Broad range of activity including the <i>Mucorales</i>
Itraconazole	100–400 mg/day orally in one or two doses with a meal or carbonated beverage	No	Variable	Nausea, hypokalemia, edema, hypertension, peripheral neuropathy	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis
Ketoconazole	200–800 mg/day orally in one or two doses with a meal or carbonated beverage	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)
Micafungin sodium	150 mg intravenously once daily (treatment); 50 mg intravenously once daily (prophylaxis)	No	Poor	Rash, rigors, headache, phlebitis	Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation
Posaconazole	400–800 mg/day orally in one or two doses (oral suspension) or 300 mg orally once daily (tablets) or 300 mg intravenously twice daily for 2 days loading dose followed by 300 mg once daily	No	Yes	Nausea, vomiting, abdominal pain, diarrhea, and headache	Broad range of activity including the <i>Mucorales</i>
Terbinafine	250 mg once or twice daily orally	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations	Dermatophytes, sporotrichosis, chromomycosis, eumycetoma
Voriconazole	200–400 mg/day orally in two doses or 12 mg/kg intravenously as loading dose for 2 days followed by 6 mg/kg/day intravenously in two doses ⁵	Yes	Yes	Transient visual disturbances, rash, photosensitivity, fluoride excess with periostitis, peripheral neuropathy, squamous cell skin cancers, hepatic enzyme elevations ⁴	All major pathogens except the <i>Mucorales</i> and sporotrichosis

¹No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.²Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.³In combination with amphotericin B.⁴Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.⁵Some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

Casposfungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive *Aspergillus* cases, *Fusarium* and *Scedosporium* infections, *Candida* esophagitis, deep *Candida* infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including the *Mucorales*. Some experts recommend therapeutic drug monitoring in individuals with severe invasive fungal infections receiving these newer azoles because of unreliable serum levels due to either metabolic alterations as a result of genetic polymorphisms (voriconazole) or erratic absorption (posaconazole). A delayed-release tablet

preparation of posaconazole provides more reliable pharmacokinetics. Isavuconazole has been approved for the treatment of aspergillosis and mucormycosis; it is available in an intravenous form that does not utilize the cyclodextrin carrier like previous azoles as well as an oral form with relatively reliable pharmacokinetic properties.

Disorders Related to Environmental Emergencies

Jacqueline A. Nemer, MD, FACEP

Marianne A. Juarez, MD

COLD & HEAT

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. In extreme temperatures, the body's thermoregulation may fail. This results in the core body temperature moving toward the temperature of the external environment. Cold and heat exposure may cause a wide spectrum of conditions; the severity varies considerably among individuals. Many of these conditions are preventable with appropriate education and planning. Preventive measures must be implemented on an individual and population level.

The likelihood and severity of extreme temperature-related conditions depend on physiologic and environmental factors. Physiologic risk factors include extremes of age; cognitive impairment; poor physical conditioning, sedentary lifestyle or immobility; poor acclimatization; concurrent injury; prior temperature-related injury; and numerous underlying medical conditions, especially those affecting cognition and thermoregulation. Pharmacologic risk factors include medications, holistic or alternative treatments, illicit drugs, tobacco, and alcohol. There is a subset of medications associated with a particularly high likelihood of worsening temperature-related conditions, such as those that impact sweating and the central nervous system and those that affect cutaneous blood flow such as peripheral vasoconstrictors or vasodilators. Environmental risk factors include changing weather conditions inadequate clothing or housing (homelessness, or housing with inadequate temperature control), and occupational or recreational exposure.

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- ▶ Spectrum of preventable heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.

- ▶ **Heat stroke:** hyperthermia with cerebral dysfunction in a patient with heat exposure.
- ▶ **Best outcome:** early recognition, initiation of rapid cooling, and avoidance of shivering during cooling.
- ▶ **Best choice of cooling method:** whichever can be instituted the fastest with the least compromise to the patient. Delays in cooling result in higher morbidity and mortality in heat stroke victims.

General Considerations

Heat-related illnesses are among the most commonly seen environmental emergencies seen in emergency departments. The amount of heat retained in the body is determined by internal metabolic function and environmental conditions, including temperature and humidity. Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. Hyperthermia results from either compromised heat dissipation mechanisms or abnormally high heat production. Heat loss occurs primarily through sweating and peripheral vasodilation. The direct transfer of heat from the skin to the surrounding air, by convection or conduction, occurs with diminishing efficiency as ambient temperature rises, especially above 37.2°C, the point at which heat transfer reverses direction. At normal temperatures, evaporation accounts for approximately 20% of the body's heat loss, but at high temperatures it becomes the major mechanism for dissipation of heat. This mechanism diminishes as humidity rises.

There is a spectrum of preventable heat-related illnesses related to environmental exposure, ranging from mild forms, such as heat cramps, to severe forms, such as heat stroke. Risk factors include longer duration of exertion, hot environment, insufficient acclimatization, and dehydration. Additional risk factors include skin disorders or other medical conditions that inhibit sweat production or evaporation, obesity, prolonged seizures, hypotension, reduced cutaneous blood flow, reduced cardiac output, the use of

drugs that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Medications that impair sweating include anticholinergics, antihistamines, phenothiazines, tricyclic antidepressants, monoamine oxidase inhibitors, and diuretics. Illicit drugs, including stimulants and some hallucinogens, and antipsychotic agents, can cause increased muscle activity and thus generate increased body heat.

Classic (nonexertional) heat-related illness may occur in any individual in a hot, relaxing environment (eg, hot bath, steam room, sunbathing, or sauna) with increased severity in individuals with the risk factors mentioned above, even despite minimal physical activity.

Heat cramping results from dilutional hyponatremia as sweat losses are replaced with water alone. **Heat exhaustion** results from prolonged strenuous activity in a hot environment without adequate water or salt intake. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

Heat syncope or sudden collapse may result in unconsciousness from volume depletion and cutaneous vasodilation with subsequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of heat syncope and may occur during or immediately following exercise. **Heat stroke**, the hallmark of which is cerebral dysfunction with core body temperature over 40°C, presents in one of two forms: classic and exertional. **Classic (nonexertional) heat stroke** occurs in patients with impaired thermoregulatory mechanisms or in extreme environmental conditions. **Exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, and taking medications that interfere with heat-dissipating mechanisms.

Clinical Findings

When diagnosing and treating heat-related illnesses, use of an internal rectal, Foley, or esophageal thermometer is necessary because the skin temperature may not accurately reflect core body temperature. **Heat cramps** are painful skeletal muscle contractions and severe muscle spasms with onset during or shortly after exercise. Examination findings typically include stable vital signs; normal or slightly increased core body temperature; moist and cool skin; and tender, hard, lumpy, painful muscles that may be twitching. The diagnosis is made clinically.

Heat exhaustion is diagnosed based on symptoms and clinical findings of a core body temperature slightly elevated but less than 40°C, tachycardia, and moist skin. Symptoms are similar to those of heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Heat syncope generally occurs in the setting of prolonged vigorous physical activity or prolonged standing in

a hot humid environment followed by a sudden collapse. Physical examination may reveal cool and moist skin, a weak pulse, and low systolic blood pressure.

Heat stroke is a life-threatening emergency. The hallmark of heat stroke is cerebral dysfunction when the core body temperature is over 40°C. Presenting symptoms include all findings seen in heat exhaustion with additional neurologic symptoms such as dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. Physical examination findings may be variable and therefore unreliable. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Providers must be vigilant in monitoring for kidney injury, liver failure, metabolic derangements, respiratory compromise, coagulopathy, and ischemia. Initial laboratory findings are nonspecific to this condition.

Treatment

A. Heat Cramps

The patient must be moved to a shaded, cool environment and given oral rehydration solution to replace both electrolytes and water. *Oral salt tablets are not recommended.* The patient may have to rest for at least 2 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

B. Heat Exhaustion

Treatment consists of moving patients to a shaded, cool environment, providing adequate fluid and electrolyte replacement, and initiating active cooling measures if necessary. Physiologic saline or isotonic glucose solution may be administered intravenously when oral administration is not appropriate. At least 48 hours of rest and rehydration are recommended.

C. Heat Syncope

Treatment consists of rest and recumbency in a shaded, cool place, and fluid and electrolyte replacement by mouth, or intravenously if necessary.

D. Heat Stroke

Initially, the patient's ABCs (airway, breathing, circulation) must be addressed and stabilized, then treatment is aimed at rapidly reducing the core body temperature within 1 hour while supporting circulation and perfusion. Patients should be observed using pulse oximetry and cardiac monitors while continuing to measure core body temperature and fluid input and output. The patient should also be observed for complications such as hypovolemic or cardiogenic shock, metabolic abnormalities, cardiac arrhythmias, coagulopathy, acute respiratory distress syndrome (ARDS), hypoglycemia, rhabdomyolysis, seizures, organ dysfunction, infection, and severe edema that can progress to a compartment syndrome. Circulatory failure in heat-related illness is mostly due to shock from relative or absolute

hypovolemia. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Clinicians must also assess for and treat concurrent conditions such as infection, trauma, and drug effects.

Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Evaporative cooling is preferred for nonexertional heat stroke and conductive-based cooling for exertional heat stroke. **Evaporative cooling** is a noninvasive, effective, quick and easy way to reduce temperature. This is accomplished by placing the undressed patient in lateral recumbent position or supported in a hands-and-knees position to expose maximum skin surface to the air while the entire undressed body is sprayed with lukewarm water (20°C) and cooled by large fans circulating room air. Addition of inhaled cool air or oxygen may aid in cooling but must not be used alone. **Conductive-based cooling** involves cool fluid infusion, gastric or bladder lavage, ice packs, and immersion into ice water or cool water. When immersion in ice water or cold water is available in the field, it is the preferred method of cooling for exertional heat stroke. Ice packs are most effective when covering the whole body, as opposed to the traditional method of placing in the axilla and groin only. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have been successful in reducing core body temperature.

Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications can be used to suppress shivering including magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.* Treatment must be continued until the core body temperature drops to 39°C.

▶ Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals may take steps to reduce personal risk factors and to gradually acclimatize to hot environments.

Coaches, athletic trainers, athletes, and parents of young athletes must be educated about heat-related illness, specifically about prevention, risks, symptoms and signs, and treatment. Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase the risk of heat-related disorders.

Those who are physically active in a hot environment must increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. *It is not recommended to have salt tablets available for use because of the risk of hypertonic hyponatremia.* Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments.

▶ Prognosis

Mortality is high from heat stroke, most frequently secondary to multiorgan dysfunction. The patient is also at risk for rhabdomyolysis, ARDS, and inflammation even after temperature has normalized. Following heat stroke, immediate reexposure to ambient heat must be avoided.

▶ When to Refer

Potential consultants include a surgeon for suspicion of compartment syndrome, nephrologist for kidney injury, and transplant surgeon for fulminant liver failure.

▶ When to Admit

All patients with suspected heat stroke must be admitted to a hospital with intensive care capability for close monitoring.

ACCIDENTAL SYSTEMIC HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Systemic hypothermia is a core body temperature below 35°C.
- ▶ Accurate core body temperature measurement must be obtained using a low-reading core temperature probe that measures as low as 25°C.
- ▶ Core body temperature must be over 32°C before terminating resuscitation efforts.
- ▶ Extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass may be considered in hypothermic patients with hemodynamic instability or cardiac arrest.

▶ General Considerations

Systemic hypothermia is defined as core body temperature below 35°C. This may be primary, from exposure to prolonged ambient, extremely low temperature, or secondary, due to thermoregulatory dysfunction. Both may be present at the same time.

Hypothermia must be considered in any patient with prolonged exposure to an ambient cold environment, especially in any patients with prior cold weather injury as well as risk factors listed in the Cold & Heat section. In prolonged or repetitive cold exposure, hypothermia ensues if the body's thermoregulatory responses become impaired.

Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient's underlying health and circumstances of cold exposure. Laboratory studies must assess acid-base status, electrolyte derangements (particularly potassium and glucose), coagulopathy, kidney failure, rhabdomyolysis and liver or pancreas dysfunction. Inaccurate laboratory values will occur if the blood sample is warmed to 37°C for testing. All patients must be evaluated for associated conditions including hypoglycemia, trauma, infection, overdose, and peripheral cold injury.

Accurate core body temperature measurements must be obtained using a low-reading core temperature probe that measures as low as 25°C. **Stage I hypothermia** is typically seen when the core body temperature is between 32°C and 35°C and is defined by shivering and possibly poor judgment or coordination but with hemodynamic stability and a normal level of consciousness. **Stage II hypothermia** correlates with core body temperature 28–32°C. Shivering stops. Bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The electrocardiogram (ECG) may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V₅, and V₆) (Figure 37–1). When the core body temperature is below 28°C, the likelihood of hemodynamic instability and cardiac arrest increase dramatically. **Stage III hypothermia** (core body temperature 24–28°C) is characterized by loss of consciousness but present vital signs. **Stage IV hypothermia** (core body

temperature less than 24°C) is the loss of vital signs. Coma, loss of reflexes, asystole, or ventricular fibrillation may falsely lead the clinician to assume the patient is dead despite reversible hypothermia.

Treatment

Rewarming is the initial, imperative treatment for all hypothermic patients. Resuscitation begins with rapid assessment and support of airway, breathing and circulation, simultaneously with the initiation of rewarming, and prevention of further heat loss. All cold, wet clothing must be removed and replaced with warm, dry clothing and blankets.

Mild or stage I hypothermia can be treated with passive external rewarming (ie, removing and replacing wet clothes with dry ones) or by active external rewarming. In contrast to those with more severe hypothermia, it is safe and recommended for the uninjured patient with mild hypothermia to become physically active to generate heat. **Active external rewarming** is noninvasive, highly effective, and safe for mild hypothermia. It involves applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Warm bath immersion limits the ability to monitor the patient or treat other coexisting conditions. Patients with mild hypothermia and previous good health usually respond well to passive and active external warming.

Stage II and III hypothermia are treated as above with the addition of more aggressive rewarming strategies. This requires close monitoring of vital signs and cardiac rhythm during rewarming. Warm intravenous fluids (38–42°C) are considered minimally invasive and effective.

As hypothermia becomes more severe, there are increased complications of both hypothermia itself and of rewarming. Complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming lactic acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation, and other cardiac arrhythmias. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient. Extreme caution must be taken when handling the hypothermic patient to avoid triggering potentially fatal arrhythmias in a phenomenon known as rescue collapse.

Treatment of patients with stage IV hypothermia cardiac arrest calls for modification of typical resuscitation algorithms. *High-quality CPR must be continued until the patient's core body temperature is at least 32°C.* There is a discrepancy between the recommendations on use and dosing of epinephrine in cardiac arrest of the severely hypothermic patient. The European Resuscitation Council recommends withholding epinephrine until warmed to 30°C, and decreasing the frequency from 30°C to 35°C. The American Heart Association permits dosage as usual in conjunction with rewarming. ECMO or cardiopulmonary bypass may be done in patients with hypothermia who are in cardiac arrest except when patients have fatal hyperkalemia (10–12 mmol/L) or evidence of death from a traumatic cause such as decapitation or asphyxiation in an avalanche.

▲ **Figure 37–1.** Electrocardiogram shows leads II and V5 in a patient whose body temperature is 24°C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers, and gradually resolve with rewarming. Osborn waves have an extra positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V₅, and V₆).

Any hypothermic patient with return of spontaneous circulation must be monitored very closely because of the high likelihood of subsequent multiorgan system failure.

▶ When to Admit

Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged emergency department observation.

HYPOTHERMIA OF THE EXTREMITIES

ESSENTIALS OF DIAGNOSIS

- ▶ Extremities suffering cold-induced injuries must not be exercised, rubbed, or massaged during rewarming.
- ▶ Rewarming of extremities affected by cold-induced injuries must be performed as soon as possible once there is no risk of refreezing.

▶ Clinical Findings

Cold exposure of the extremities produces immediate localized and then generalized vasoconstriction, which may result in a wide range of injuries. Tissue damage occurs because of ischemia and intravascular thromboses, endothelial damage, or actual freezing. Freezing (frostbite) may occur when skin temperatures drop or in the presence of wind, water, immobility, malnutrition, or vascular disease.

▶ Prevention

“Keep warm, keep dry, and keep moving.” For optimal prevention of frostbite, individuals must wear warm, dry clothing. Arms, legs, fingers, and toes must be exercised to maintain circulation. Wet clothing, socks, and shoes must be replaced with dry ones. Those most at risk are people with underlying diseases or medications that decrease tissue perfusion and those with environmental exposure to a prolonged cold environment. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

FROSTNIP & CHILBLAIN (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury causing local paresthesias of the involved area that completely resolve with passive external rewarming.

Chilblains or **erythema pernio** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma, secondary infection, and further cold exposure.

IMMERSION FOOT OR TRENCH FOOT

Immersion foot (or hand) is caused by prolonged immersion in cold water or mud, usually below 10°C. **Prehyperemic stage** is marked by early symptoms of cold and anesthesia of the affected area. **Hyperemic stage** follows with a hot sensation, intense burning, and shooting pains. **Posthyperemic stage** occurs with ongoing cold exposure; the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm. This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene.

Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid further cold injury and water immersion. Affected parts are elevated to aid in removal of edema fluid. Pressure sites are protected with cushions. Bed rest is required until all ulcers have healed.

FROSTBITE

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows reperfusion of the frozen tissues, with damaged endothelial cells and progressive microvascular thrombosis resulting in further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved. Symptoms include numbness, prickling, itching, and pallor. With increasing severity, deeper structures become involved. The skin appears white or yellow, loses elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, gangrene, paresthesias, and stiffness may occur.

▶ Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia, concurrent conditions, and injury. Avoid secondary exposure to cold. Early use of systemic analgesics is recommended for nonfrozen injuries. Hydrate patients orally or parenterally to avoid hypovolemia and to improve perfusion.

1. Rewarming—Rapid rewarming at temperatures slightly above normal body temperature may significantly decrease

tissue necrosis and reverse the tissue crystallization. **If there is any possibility of refreezing, the frostbitten part must not be thawed.** Ideally, the frozen extremity must not be used. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. In the absence of a thermometer, the temperature may be checked by an unaffected extremity, ideally of a caregiver rather than the patient. Water in this temperature range feels warm but not hot to the normal hand or wrist. If warm water is not available, then passive thawing in a warm environment must be allowed. Dry heat is not recommended because it is more difficult to regulate and increases the likelihood of accidental burns. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. **In the early stage, rewarming by exercise, rubbing, or friction is contraindicated.** The patient must be kept at bed rest with the affected parts elevated and uncovered at room temperature. Avoid application of casts, occlusive dressings, or bandages. Blisters must be left intact unless signs of infection supervene.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis status must be verified and updated as needed. Infection risk may be reduced by aseptic wound care. Non-adherent sterile gauze and fluffy dressing must be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically.

B. Medical and Surgical Treatment Options

With the availability of telemedicine, specialists are able to provide advice on early field treatment of cold-injured patients in remote areas, thereby improving outcomes. Clinicians must watch for evidence of compartment syndrome and need for fasciotomy. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Rates of amputation have been reduced with the use of intravenous infusions of synthetic prostaglandins and of a tissue plasminogen activators, and with intra-arterial administration of a thrombolytic within 24 hours of exposure. There is insufficient evidence to recommend hyperbaric oxygen, heparin, or sympathectomy.

C. Follow-Up Care

Patient education must include ongoing care of the cold injury and prevention of future hypothermia and cold injury. Gentle, progressive physical therapy to promote circulation should be instituted as tolerated. Debridement and amputation may be considered only after it is established that the tissues are necrotic.

► Prognosis

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved

extremity may be at increased susceptibility for discomfort and injury upon re-exposure to cold. Neuropathic sequelae include pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities. Nerve conduction abnormalities may persist for many years after a cold injury.

► When to Admit

- Management of tissue damage, comorbidities, associated injuries.
- Need for hospital-based interventions.
- Psychosocial factors (cognitive impairment, inadequate living situation) that could compromise patient safety or recovery.

▼ DROWNING

ESSENTIALS OF DIAGNOSIS

- The first requirement of rescue is immediate rescue breathing and CPR.
- Clinical manifestations include hypoxemia, pulmonary edema, and hypoventilation.
- The patient must also be assessed for hypothermia, hypoglycemia, alcohol intake, concurrent injuries, and medical conditions.

► General Considerations

Drowning, as defined by the World Health Organization, is the “process resulting in primary respiratory impairment from submersion in a liquid medium.” Drowning may result in aspiration, laryngospasm, hypoxemia, and acidemia. Outcomes from drowning range from life without morbidity to death. Morbidity may be immediate or delayed. The asphyxia of drowning is usually due to aspiration of fluid, but it may result from airway obstruction caused by laryngeal spasm while the victim is gasping under water. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours. Disseminated intravascular coagulation may also lead to bleeding after asphyxiation from drowning.

Clinical Findings

A. Symptoms and Signs

The patient's appearance may vary from asymptomatic to marked distress with abnormal vital signs. Symptoms and signs include dyspnea, cough, wheezing, chest pain, dysrhythmia, hypotension, cyanosis, and apnea. The patient may experience headache, neurologic deficits, and altered level of consciousness. Hypothermia is highly likely with cold water or prolonged submersion.

B. Laboratory Findings

Metabolic acidosis is common and arterial blood gas results may be helpful in determining the degree of injury since initial clinical findings may appear benign. PaO_2 is usually decreased; PaCO_2 may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario.

Prevention

Education and prevention are critical given the high burden of disease from drowning.

Preventive measures must be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the use of alcohol or other drugs, inadequate water safety skills, poor physical health, hyperventilation, sudden acute illness, acute trauma, venomous stings or bites, decompression sickness, dangerous water conditions, and carbon monoxide exposure from boat motors.

Treatment

A. First Aid

1. *The first requirement of rescue is immediate basic life support treatment and CPR.* At the scene, immediate measures to combat hypoxemia are critical to improve outcome.
2. Patient must be assessed for hypothermia, hypoglycemia, concurrent medical conditions, and associated trauma, especially brain and cervical spine injury.
3. Rescuer must not attempt to drain water from the victim's lungs.
4. Resuscitation and basic life support efforts must be continued until core body temperature reaches 32°C.

B. Subsequent Management

1. Ensure optimal ventilation and oxygenation—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen must be administered immediately at the highest available concentration. Oxygen saturation must be maintained at 90% or higher via supplemental oxygen, continuous positive airway pressure (CPAP), positive end-expiratory pressure (PEEP) or intubation and mechanical ventilation.

Serial physical examinations and chest radiographs must be performed to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing. Nasogastric suctioning can decompress the stomach.

2. Cardiovascular support—Intravascular volume status must be monitored and supported by vascular fluid replacement, vasopressors, or diuretics as needed.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in 70% of drowning victims, but this typically corrects through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral and spinal cord injury—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock.

5. Hypothermia—Core body temperature must be measured and managed as appropriate (see Accidental Systemic Hypothermia, above).

Course & Prognosis

Respiratory damage is often severe in the minutes to hours following a drowning. With respiratory supportive treatment, improvements typically occur quickly over the first few days following the drowning. Long-term complications of drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. Prognosis is directly correlated with the patient's age, submersion time, rapidity of prehospital resuscitation and subsequent transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

When to Admit

Most patients with significant drowning or concurrent medical or traumatic conditions require inpatient monitoring following the event. This includes continuous monitoring of cardiorespiratory, neurologic, renal and metabolic function. Pulmonary edema may not appear for 24 hours.

THERMAL BURNS

ESSENTIALS OF DIAGNOSIS

- Estimates of the burn location, size, and depth greatly determine treatment plan.
- The first 48 hours of burn care offer the greatest impact on morbidity and mortality of a burn victim.

Worldwide, burns are a common cause of injury and potential morbidity and mortality. Burn prognosis is affected by the type of environment where the burn occurred. Low-resource settings (wilderness or low-income areas) are associated with delays in and suboptimal access to standard burn treatments.

The first 48 hours after thermal burn injury offer the greatest opportunity to impact the survival of the patient. Early surgical intervention, wound care, enteral feeding, glucose control and metabolic management, infection control, and prevention of hypothermia and compartment syndrome have contributed to significantly lower mortality rates and shorter hospitalizations. Research utilizing several different well-established burn severity scores has shown the importance of patient comorbidities to the prognosis of patients with severe burn injuries.

General Considerations

A. Classification

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since these estimations will quantify the parameters of resuscitation.

1. Extent—In adults, the “rule of nines” (Figure 37–2) is useful for rapidly assessing the extent of a burn. It is important to view the entire patient to make an accurate assessment of skin findings on initial and subsequent examinations. One rule of thumb is that the palm of an open hand of the patient constitutes 1% total body surface area (TBSA) in adults. Partial- and full-thickness burns are included in calculating the TBSA.

▲ **Figure 37–2.** Estimation of body surface area in burns.

2. Depth—Judgment of depth of injury is difficult. **Superficial burns** (previously referred to as first-degree burns) may be red or gray but will demonstrate excellent capillary refill and are not blistered initially. If the wound is blistered and appears pink and wet, this represents a **superficial partial-thickness burn** (previously, second-degree burn). **Deep partial-thickness burns** appear white and wet, and they bleed if poked; cutaneous sensation is maintained. **Full-thickness burns** (previously, third-degree burns) result in a loss of adnexal structures and may appear white-yellow in color, or may have a black charred appearance, and its stiff, dry skin does not bleed when poked; cutaneous sensation is lost.

Deep partial-thickness and full-thickness burns are treated in a similar fashion. Neither will heal appropriately without early debridement and grafting; without such treatment, the resultant skin is thin and scarred.

B. Survival After Burn Injury

Transfer to a burn unit is determined by large burn size, circumferential burn, or burn involving a joint or high-risk body part, and by comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support.

C. Associated Injuries or Illnesses

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Severe burns from any source may result in similar complications (ie, infections, respiratory compromise, multiorgan dysfunction, venous thromboembolism, and gastrointestinal complications).

D. Systemic Reactions to Burn Injury

When burns greater than approximately 20% of TBSA are present, systemic metabolic derangements may occur and require intensive support. The inflammatory cascade can result in shock and coagulopathy.

Treatment

A. Initial Resuscitation

1. Primary survey—Burn patients require a full trauma assessment, starting with “ABCDE” (airway, breathing, circulation, disability, exposure).

A. AIRWAY CONTROL—Serial assessments of airway and breathing are necessary because airway compromise and ARDS may develop, particularly in those with inhalation injury.

B. VASCULAR ACCESS—Vascular access must be obtained on all burn patients.

C. FLUID RESUSCITATION—Patients with burns of greater than 15% of TBSA require intravascular fluid administration of large volumes of crystalloid. The most widely recognized

guideline for fluid resuscitation is the **Parkland formula** (<http://www.mdcalc.com/parkland-formula-burns/>) in which the fluid requirement in the first 24 hours is estimated as $4 \text{ mL/kg} \times \text{body weight per percent of body surface area burned}$. Half the calculated fluid is given in the first 8-hour period from the time of injury, not the time of arrival to medical care. The remaining fluid is delivered over the next 16 hours. An extremely large volume of fluid may be required. Crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock. Conversely, clinicians must watch for clinical signs of volume overload as it may lead to pulmonary complications and to a compartment syndrome from edema. Electrical burns and inhalation injury may increase the fluid requirement.

B. Management

1. Pain control—Pain control is critical in these patients. Treatment is with (oral or intravenous) nonsteroidal anti-inflammatory drugs and opioids.

2. Chemoprophylaxis—

A. TETANUS IMMUNIZATION—Tetanus prophylaxis status needs to be verified and updated in all burn patients. (See Chapter 33.)

B. ANTIBIOTICS—All nonsuperficial wounds need to be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

3. Surgical management—

A. ESCHAROTOMY—As tissue swelling occurs, ischemia may develop under any constricting eschar of an extremity, neck, chest, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the eschar can save life and limb.

B. FASCIOTOMY—Fasciotomy is indicated for any compartment syndrome. Clinicians must frequently monitor patients for development of early signs of a compartment syndrome, particularly in those with circumferential burns.

C. DEBRIDEMENT, DRESSINGS, AND TOPICAL AND SYSTEMIC ANTIBIOTIC THERAPY—Minor burn wounds must be debrided to determine the depth of the burn and then thoroughly cleansed. Thereafter, daily wound care must consist of debridements as needed, topical antibiotics, and wound dressings. Patient compliance and adequate pain control is essential for successful outpatient treatment. The wound must be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is a critically important intervention. Topical antibiotics may be applied after wound cleansing. Silver sulfadiazine is no longer recommended.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, therefore close monitoring and early treatment for systemic infection is imperative. Health care–associated infections are increasingly common.

D. WOUND MANAGEMENT—The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that do not heal spontaneously in 7–10 days (ie, deep partial-thickness or full-thickness burns) are best treated by a specialist through excision and autograft; otherwise, granulation and infection may develop, and the quality of the skin in regenerated deep partial thickness burns is marginal because of the very thin dermis that emerges.

Cultured allogeneic keratinocyte grafts can provide rapid early coverage for superficial burn injuries. With severe burns, skin substitution with cultured grafts can be lifesaving. However, although the replaced dermis does have nearly normal histologic dermal elements, there are no adnexal structures present and very few, if any, elastic fibers.

E. ABDOMINAL COMPARTMENT SYNDROME—Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients with mortality rates of approximately 60% despite surgical intervention. Diagnosis is confirmed by bladder pressures greater than 30 mm Hg in at-risk patients. Surgical abdominal decompression may improve ventilation and oxygen delivery but may not impact survival.

C. Patient Support

Burn patients require extensive supportive care, both physiologically and psychologically. It is important to maintain normal core body temperature and avoid hypothermia (by maintaining environmental temperature at or above 30°C) in patients with burns over more than 20% of TBSA. Burn patients are at risk for many complications such as respiratory injury, ARDS, sepsis, multiorgan failure, and venous thromboembolism.

Burn patients have increased metabolic and energy needs for wound healing and require careful assessment and provision of optimal nutrition. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

Occasionally, ARDS or respiratory failure unresponsive to maximal ventilatory support may develop in burn patients.

Prevention of long-term scars remains a formidable problem in seriously burned patients.

► Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia is a predictor of worse outcomes. Common complications include sepsis; gangrene requiring limb amputation; or neurologic, cardiac, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following burn injury.

► When to Refer

- Transfer to a burn unit is indicated for large burn size (for partial-thickness burns, greater than 10% of TBSA or for full-thickness burns, greater than 5% of TBSA), circumferential burn, inhalation injury, or burn involving a joint or high-risk body part (face, hands, feet, genitalia), and for patients with comorbidities.

▶ When to Admit

- All burn patients require extensive supportive care, both physiologically and psychologically.
- Significant burns (based on location and extent).
- Patients with significant comorbidities and suboptimal home situations.
- Burn center consultation can advise which patients require transfer and which can be managed via telemedicine/telephone consultation.
- Monitoring includes vital signs, wound care, and observation for potential complications of electrolyte abnormalities, acute kidney injury, hepatic failure, cardiopulmonary compromise, hypoglycemia, and infection.

ELECTRICAL INJURY

ESSENTIALS OF DIAGNOSIS

- ▶ Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- ▶ Clinical findings of death are unreliable; therefore, resuscitation efforts must be attempted before assuming the electrical injury victim is dead.
- ▶ Skin findings may be misleading and are not indicative of the degree of deeper tissue injury.

▶ General Considerations

Electricity-induced injuries are common and yet most are preventable. These injuries occur by exposure to electrical current of low voltage, high voltage, or lightning. Electrical current type is either alternating current (AC) or direct current (DC). Electricity causes acute injury by direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and associated trauma.

Alternating current (AC) is an electric current that periodically reverses direction in a sine wave pattern and may cause muscle tetany, which prolongs the duration and amount of current exposure. AC can be low voltage or high voltage. Most households and businesses use electric power in the form of AC at **low voltages** (less than 1000 V). Low voltage electrical injuries can range from minor to

significant damage and death. **High voltage** (greater than 1000 V) electrical injuries are often related to occupational exposure and associated with deep tissue damage and higher morbidity and mortality. **Direct current (DC)** is unidirectional electrical flow (ie, lightning, batteries, and automotive electrical systems). It is more likely to cause a single intense muscle contraction and asystole. **Lightning** differs from other high-voltage electrical shock in that lightning delivers a direct current of millions of volts in a fraction of a second.

The extent of damage from electrical injuries depends on the following factors: voltage, current type, tissue resistance, moisture, pathway, duration of exposure, associated trauma, and comorbidities. Current is the most important determinant of tissue damage. Current passes through the tissues of least resistance as energy which produces heat and causes direct thermal injury. Tissue resistance varies throughout the body with nerve cells being the most vulnerable, and bone, the most resistant to electrical current.

▶ Clinical Findings

Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current.

Skin damage does not correlate with the degree of injury. Not all electrical injuries cause skin damage; very minor skin damage may be present with massive internal injuries. Symptoms and signs may range from very subtle to death. The presence of entrance and exit burns signifies an increased risk of deep tissue damage. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. If the current passes through the heart or brainstem, death may be immediate due to ventricular fibrillation, asystole, or apnea.

Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive and unreliable.

▶ Complications

Complications include cardiac or respiratory arrest; dysrhythmias; neurologic dysfunction, such as autonomic dysfunction (resulting in pupils that are fixed, dilated, or asymmetric); altered mental status; seizures; paralysis; headache; vascular injury; tissue edema and necrosis; compartment syndrome; associated traumatic injuries (ruptured ear drums, fractures); pneumothorax; rhabdomyolysis; acute kidney injury; hypovolemia; infections; ocular complications; sepsis; gangrene; cognitive or psychiatric dysfunction. Psychiatric support may be necessary following electrical injury.

▶ Treatment

A. Emergency Measures

The patient must be assessed and treated as a trauma victim. The victim must be safely separated from the electrical current prior to initiation of CPR or any treatment. *Resuscitation must then be initiated since clinical findings of death are unreliable.*

B. Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by a full trauma protocol. Fluid resuscitation is important to maintain adequate urinary output. Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, kidney function tests, liver chemistries, creatine phosphokinase or urine myoglobin, urinalysis, and cardiac enzymes. ECG does not show typical patterns of ischemia since the electrical damage is epicardial. Victims must be evaluated for hidden injury, organ injury, blunt trauma, dehydration, skin burns, hypertension, acid-base disturbances, and neurological as well as psychological damage.

Electrical burn wounds are an underrecognized and yet devastating form of burn injury with wide-ranging and significant complications.

When electrical injury occurs, there must be a high suspicion for extensive deep tissue necrosis. Superficial skin may appear deceptively benign, leading to a delayed or completely overlooked diagnosis of deep tissue injury. Deep tissue necrosis leads to profound tissue swelling, which results in a high risk of a compartment syndrome. Early debridement of devitalized tissues and tetanus prophylaxis may reduce the risks of infection.

Pain management is important before, during, and after initial treatment and subsequent rehabilitation.

► Prognosis

Prognosis depends on the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications.

► When to Refer

- Specialists may be needed to perform fasciotomy for compartment syndrome or devitalized tissue debridement or microvascular reconstruction.
- Ophthalmologists should evaluate patients for possible ocular complications, and subsequent ENT physicians should evaluate for tympanic membrane rupture or hearing loss.

► When to Admit

Indications for hospitalization include high-voltage exposure; dysrhythmia or ECG changes; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

RADIATION EXPOSURE

ESSENTIALS OF DIAGNOSIS

- Damage from radiation is determined by the source, type, quantity, duration, bodily location, and susceptibility and accumulation of exposures of the person.
- Clinicians and patients must be educated regarding the risks of medical diagnostic radiation. These radiation risks must be weighed against the benefits of the medical imaging needed.

► General Considerations

Radiation exposure may occur from environmental, occupational, medical care, accidental, or intentional causes. The extent of damage from radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; the degree of disruption to DNA; metabolic and cellular function; and the age, underlying condition, susceptibility, comorbidities, and accumulative exposures of the victim.

Radiation occurs from both nonionizing and ionizing radiation sources. **Nonionizing radiation** is low energy, resulting in injuries related to local thermal damage (ie, microwave, ultraviolet, visible light, and radiowave). **Ionizing radiation** is high energy, causing bodily damage in several ways. Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate (ie, alpha or beta particles, neutrons, and protons). Exposure may be external, internal, or both.

International Commission on Radiological Protection (ICRP) website provides the most up-to-date recommendations for protection against ionizing radiation (<http://www.icrp.org/index.asp>). The World Health Organization (WHO) has published a series of guidelines on radiation emergencies (eg, see http://www.who.int/ionizing_radiation/a_e/en/). These guidelines include recommended interventions during the early, intermediate, and late emergency phases and the management of their psychosocial impact.

► Clinical Findings

Radiation exposure results in acute and delayed effects. Acute effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). This may be manifested as mucositis, nausea, vomiting, gastrointestinal edema and ulcers, skin burns, and bone marrow suppression over hours to days after exposure. Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction.

Andrews CJ et al. Neurological and neuropsychological consequences of electrical and lightning shock: review and theories of causation. *Neural Regen Res*. 2017 May;12(5):677–86. [PMID: 28616016]

Clark AT et al. JAMA patient page. Electrical injury. *JAMA*. 2017 Sep 26;318(12):1198. [PMID: 28973623]

Davis C et al. Wilderness Medical Society practice guidelines for the prevention and treatment of lightning injuries: 2014 update. *Wilderness Environ Med*. 2014 Dec;25(4 Suppl):S86–95. [PMID: 25498265]

Clinicians must be educated to recognize and treat acute radiation sickness also referred to as **acute radiation syndrome**. Acute radiation syndrome is due to an exposure to high doses of ionizing radiation over a brief time course. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases, prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow. The Centers for Disease Control and Prevention offers web-based information regarding acute radiation syndrome (<https://emergency.cdc.gov/radiation/arsphysicianfactsheet.asp>).

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, cardiopulmonary, and cerebrovascular symptoms and signs from initial exposure and over time.

► Therapeutic Radiation Exposure

Radiation therapy has been a successful component in the treatment of many malignancies. These radiation-treated cancer survivors have a higher risk of development of a second malignancy; obesity; and pulmonary, cardiac and thyroid dysfunction as well as an increased overall risk for chronic health conditions and mortality.

► Medical Imaging Radiation Exposure

Medical imaging with ionizing radiation exposure has dramatically increased over the past few decades. Medical imaging radiation exposure is a growing concern for the health care professionals and the public. With the rising use of medical imaging, there are urgent safety needs for standardization and regulation of radiation dosing in medical diagnostics and for clinician and public education about this issue.

The American College of Radiology (ACR) offers “ACR Appropriateness Criteria” which are evidence-based guidelines created by expert panels to serve as a reference for best practices for imaging decisions by health care providers (<https://www.acr.org/Clinical-Resources/ACR-Appropriateness-Criteria>). Clinicians and patients must carefully weigh the risks and benefits of radiation exposure when deciding on an imaging test.

► Occupational & Environmental Radiation Exposure

The National Nuclear Security Administration’s Radiation Emergency Assistance Center provides 24-hour access to expert consultation services over the telephone or via email (telephone: 1-865-576-1005 or email: <https://orise.orau.gov/reacts/>). The Centers for Disease Control and Prevention “Radiation Emergency” website (<http://emergency.cdc.gov/radiation/>) is a useful resource for professionals.

► Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatments focus on the dose, route, and effects of exposure.

► Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Death is usually due to hematopoietic failure, gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection.

Carcinogenesis is related to the radiation type, total dose, duration, accumulation of exposure, and to the susceptibility of the victim. The younger the victim’s age at the time of exposure, the greater the risk of acute and long-term damage from radiation. Radiation-related cancer risks persist throughout the exposed person’s life span.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is a growing concern for the iatrogenic increase in radiation-induced cancer risks. There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

► When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.

ENVIRONMENTAL DISORDERS RELATED TO ALTITUDE

DYSBARISM & DECOMPRESSION SICKNESS

ESSENTIALS OF DIAGNOSIS

- Symptoms temporally related to recent altitude or pressure changes.
- Early recognition and prompt treatment of decompression illness are extremely important.
- Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

General Considerations

Dysbarism and decompression illness are physiologic problems that result from altitude changes and the effects of environmental pressure on the gases in the body during underwater descent and ascent. These are most likely to occur when scuba diving is followed closely by travel to high altitudes, or when the scuba diver is not adherent to the conservative dive guidelines for dive duration, course, depth, and surface times.

As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. During the ascent, gases in the body expand.

Dysbarism results from barotrauma when gas compression or expansion occurs in parts of the body that are noncompressible or have limited compliance. Pulmonary overinflation syndrome is one of the most serious and potentially fatal results of barotrauma. This syndrome is due to an inappropriately rapid ascent causing alveoli rupture and air bubble extravasation into tissue planes or even the cerebral circulation.

Decompression illness occurs when the ascent is too rapid and gas bubbles form and cause damage depending on their location (ie, coronary, pulmonary, spinal or cerebral blood vessels, joints, soft tissue). Decompression illness symptoms depends on the size and number and location of gas bubbles released (notably nitrogen). Risk of decompression illness depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver's age, weight, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude (scuba dive) and high altitude (air travel or ground ascent). Predisposing factors include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver's overall health, dehydration, alcohol and medication effects, and panic attacks. Decompression illness may also occur in those who take hot showers after cold dives. There have been clinical case reports of delayed decompression illness presentation following post-dive exercise.

Preventive measures include diver education; pre-dive medical screening and dive planning; strict adherence to dive course, timing, and depths; and a slow and controlled ascent plus proper control of buoyancy. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive, especially following multiple dives.

Clinical Findings

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 48 hours later. Decompression illness symptoms include pain in the joints ("the bends"); skin pruritus or burning (skin bends); cardiac symptoms (acute coronary syndrome, conduction abnormalities); spinal cord or cerebral symptoms (focal neurologic dysfunction or "dissociation" symptoms that do not follow typical distribution neuroanatomy patterns); labyrinthine decompression illness ("the staggers,"

central vertigo); pulmonary decompression illness ("the chokes," inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear and sinus; coma and death.

Decompression illness involving the brain and spinal cord may occur by different mechanisms due to air bubbles causing arterial occlusion, venous obstruction, or in situ toxicity.

The clinician must assess for associated conditions of hypothermia, hypoglycemia, hypovolemia, drowning, trauma, envenomations, or concurrent medical conditions.

Treatment

Early recognition and prompt treatment are extremely important. Decompression illness must be considered if symptoms are temporally related to recent diving or altitude or pressure changes within the past 48 hours. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Hyperbaric oxygen treatment is commonly recommended for decompression illness symptoms. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild decompression illness symptoms resolve. Nonsteroidal anti-inflammatory drugs, acetaminophen or aspirin may be given for pain control if there are no contraindications. *Opioids must be used very cautiously*, since these may obscure the response to recompression.

When to Admit

Rapid transportation to a hyperbaric treatment facility for recompression is imperative for decompression illness. The Divers Alert Network is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org).

HIGH-ALTITUDE ILLNESS

ESSENTIALS OF DIAGNOSIS

- ▶ The severity of the high-altitude illness is affected by the rate and height of ascent, and the individual's susceptibility.
- ▶ Prompt recognition and medical treatment of early symptoms of high-altitude illness may prevent progression.

- ▶ Clinicians must assess other conditions that may coexist or mimic symptoms of high-altitude illness.
- ▶ Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

▶ General Considerations

As altitude increases, hypobaric hypoxia results due to a decrease in both barometric pressure and oxygen partial pressure. High-altitude illnesses are due to hypobaric hypoxia at high altitudes (usually greater than 2000 meters or 6562 feet). High-altitude illness includes a spectrum of disorders categorized by end-organ effects (mostly cerebral and pulmonary), and exposure duration (acute and long-term). Acute high-altitude illnesses are **acute hypoxia**, **acute mountain sickness (AMS)**, **high-altitude cerebral edema (HACE)**, and **high-altitude pulmonary edema (HAPE)**.

Acclimatization occurs as a physiologic response to the rise in altitude and increasing hypobaric hypoxia. High-altitude illness results when the hypoxic stress is greater than the individual's ability to acclimatize. Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility, and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors (rapid rate and height of ascent and total change in altitude).

Individual susceptibility factors include underlying conditions such as cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders, pregnancy, neurologic conditions, recent surgery, diabetes and many other chronic medical conditions, and cigarette smoking. Those with symptomatic cardiac or pulmonary disease must avoid high altitudes.

Patient assessment for high-altitude illness must also include evaluation for other conditions, which may coexist or may present in a similar manner.

1. High-Altitude–Associated Neurologic Conditions: AMS & HACE

There is a spectrum of neurologic conditions caused by high altitude, ranging from **acute mountain sickness (AMS)** to the more serious form **high-altitude cerebral edema (HACE)**. Clinicians may utilize various diagnostic tools to assess the level of cerebral impairment due to high altitude.

AMS includes symptoms such as headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, difficulty sleeping. Later symptoms include irritability, difficulty concentrating, anorexia, insomnia, and increased headaches.

HACE includes the severe symptoms of AMS and results from cerebral vasogenic edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters

(8202 feet) but may occur at lower elevations. Hallmarks are altered mental status, ataxia, severe lassitude, and encephalopathy. Examination findings may include confusion, ataxia, urinary retention or incontinence, focal neurologic deficits, papilledema, and seizures. Symptoms may progress to obtundation, coma, and death.

▶ Treatment

Definitive treatment is immediate descent of at least 610 meters (2001 feet), and descent must continue until symptoms improve. Descent is essential if the symptoms are persistent, severe, worsening or if HACE or HAPE are present. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief, but they must not delay descent.

Initial treatment involves oxygen administration to keep the pulse oximetry S_pO_2 to greater than 90%.

Acetazolamide (250 mg twice daily) is an effective medication for both prophylaxis and treatment of mild symptoms of AMS.

Dexamethasone is given for moderate to severe AMS (4 mg orally every 6 hours). Dexamethasone is the primary treatment for HACE (8 mg once then 4 mg every 6 hours). Acetazolamide can be added as an adjunct in severe HACE cases. In most individuals, symptoms clear within 24–48 hours. HACE treatment must continue until 24 hours after resolution of symptoms or until descent is completed. Dexamethasone should not be given for longer than 7 days.

It is imperative that the clinician also assess for other conditions that may mimic or coexist with AMS and HACE.

If HAPE symptoms and signs are present along with HACE, nifedipine or a selective phosphodiesterase inhibitor may be added for pulmonary vasodilation. The clinician must be cautious when using combinations of vasodilators.

2. Acute HAPE

HAPE is the leading cause of death from high-altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at altitudes above 3000 meters (9840 feet), although it may occur at lower levels. Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion must be avoided. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens.

Physical findings may include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, rales, and rhonchi. The clinician must assess for other potential medical conditions because the clinical picture may resemble other entities. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. Prompt recognition and medical attention of early symptoms of HAPE may prevent progression.

Treatment

Immediate descent (at least 610 meters [2000 feet]) is essential, although this may not be immediately possible and may not alone improve symptoms.

The patient must rest, reclined with head elevated. Supplemental oxygen must be administered to maintain pulse oximetry reading S_pO_2 greater than 90%. Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible, but must not delay descent.

Nifedipine (60-mg slow extended-release tablets daily, given in divided doses) can be used as an adjunct if the other therapies (descent, oxygen, or portable hyperbarics) are not successful or available. Selective phosphodiesterase inhibitors may be used for HAPE prevention but may also provide effective symptom relief as an alternative or if nifedipine is not available. *Administering nifedipine plus a phosphodiesterase inhibitor as pulmonary vasodilators is not recommended* because this combination may also lower the mean arterial pressure and decrease cerebral perfusion. Treatment for ARDS (see Chapter 9) is required for some patients. If neurologic symptoms are present concurrently with HAPE and do not resolve with improved oxygenation, dexamethasone may be added according to HACE treatment guidelines.

3. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at high altitudes (above 4500 meters) for a prolonged period of time. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

4. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such a hypobaric hypoxic environment. It is difficult to differentiate from chronic pulmonary disease.

Prevention of High-Altitude Disorders

Pre-trip preventive measures include participant education, medical preparticipation evaluation, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel and during the trip. Preventive efforts during ascent include reduced food intake and avoidance of alcohol, tobacco, and unnecessary physical activity during travel.

Gradual ascent is the most effective way to allow acclimatization. Low-risk ascension rate is 2 or more days to arrive at 2500–3000 meters. The altitude reached during waking hours is not as important as the altitude at which the hiker sleeps. If the terrain does not allow a sleeping elevation increase below 500 meters, an extra rest day must be added before or after the increased sleep elevation more than 500 meters.

Drug prophylaxis may be prescribed for AMS and HACE if no contraindications exist. Prophylactic low-dose acetazolamide (125 mg twice daily orally) has been shown to reduce the incidence and severity of AMS and HACE

when started 3 days prior to ascent and continued for 48–72 hours at high altitude. Dexamethasone is an alternative prophylactic medication for AMS and HACE.

Individuals with a past history of HAPE should use drug prophylaxis to reduce the risk of recurrence. Nifedipine started the day before ascent and continued through the fourth day at target elevation, or through the seventh day if the ascent rate was faster, is recommended. Salmeterol can be added beginning 24 hours prior to ascent. This can be used as an adjunct to nifedipine but not as monotherapy.

Phosphodiesterase inhibitors may be beneficial in the treatment of HAPE based on their physiologic effects of decreased pulmonary arterial pressures and pulmonary vasodilation.

When to Admit

- All patients with HACE or HAPE must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent.
- Pulmonary symptoms and hypoxia may be worsened by complications such as pulmonary embolism, secondary respiratory infection, bronchospasm, mucous plugging, or acute coronary syndrome.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends on the nature and severity of the traveler's preflight condition and factors such as travel duration, frequency and use of in-flight exercise, cabin altitude pressure, availability of medical supplies, and presence of health care professionals on board. Air travel passengers are susceptible to a wide range of flight-related problems: pulmonary (hypoxemia, gas expansion), venous thromboembolism (VTE), infectious, cardiac, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, and substance-related. These air-travel risks are higher for those air travelers with preexisting medical conditions.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight due to cabin altitude. Despite commercial aircraft pressurization requirements,

there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers.

Any form of prolonged travel involving immobilization has been associated with increased risk of VTE (referred to as “traveler’s thrombosis”), although air travel has been the main focus of medical review. Conditions that place long-distance travelers at high risk for VTE include the following: (1) travel involving immobilization for 4 or more hours, (2) hypercoagulable disorders, and (3) acquired risks.

Air travel is not advised for anyone who is “incapacitated” or has any “unstable conditions.” The Air Transport Association of America defines an **incapacitated passenger** as “one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers.” **Unstable conditions** include active pneumothorax, advanced pulmonary hypertension, acute worsening of an underlying lung disease, poorly controlled hypertension, dysrhythmias, angina, valvular disease, heart failure, or acute psychiatric condition; severe anemia or symptomatic sickle cell disease; recent myocardial infarction; cerebrovascular accident; poorly controlled seizure disorder; deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease.

► Pregnancy

Traveling during pregnancy is becoming more common. Pregnant travelers have unique travel-related and location-specific risks. Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. A clinician’s authorization is required if travel is essential during the ninth month of pregnancy or earlier in a complicated pregnancy.

Long travel increases risk of VTE for the pregnant traveler. Pregnant travelers are at higher risk from infection transmission and air travel radiation exposure.

► Prevention

Air travel complications may be reduced by the following preventive measures: passenger prescreening, passenger education, and in-flight positioning and activity. Prescreening evaluation is recommended for all high-risk patients including preexisting requirement of oxygen, continuous positive pressure or ventilator support, underlying restrictive or obstructive lung disease, comorbidities worsened by hypoxemia, previous respiratory distress during air travel, recent pneumothorax, and recent (within 6 weeks) acute respiratory illness. Patients at risk for hypoxia must be assessed prior to air travel to determine if there is a need for supplemental in-flight oxygen.

Air travel education must include risk reduction measures for VTE, infectious diseases, and exacerbations of underlying medical conditions. Patients and clinicians can check the World Health Organization website for the most updated information on travel health risks and infectious diseases (<http://www.who.int/ith/en/>).

All long-distance travelers can reduce VTE risk by avoiding constrictive clothing, staying well-hydrated, changing position frequently, avoiding cramped position, avoiding leg crossing, engaging in frequent in-flight leg stretching exercises at least every hour, and walking for 5 minutes every hour. Clinicians must assess those with high risk of VTE prior to air travel to determine whether anticoagulation is indicated (see Table 14–14).

38

Poisoning

Kent R. Olson, MD

INITIAL EVALUATION: POISONING OR OVERDOSE

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose, but not yet exhibit any manifestations of toxicity. It is important to (1) quickly assess the potential danger, (2) consider gut and skin decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.

Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a regional poison control center. (In the United States, dialing 1-800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION

Call your regional poison control center
U.S. toll-free 1-800-222-1222

Observe the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility (eg, opioids, anticholinergics, aspirin) or may cause a delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed. Before discharge,

psychiatric evaluation should be performed to assess suicide risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *A*irway, *B*reathing, *C*irculation, and *D*rugs (dextrose, thiamine, and naloxone or flumazenil), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds to intravenous naloxone or flumazenil.

2. Breathing—Clinically assess the quality and depth of respiration and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial or venous blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory depression, bronchospasm, pulmonary aspiration, or non-cardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation, but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a pulse oximetry device capable of detecting these forms of hemoglobin is used.

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs—

A. DEXTROSE AND THIAMINE—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid point-of-care blood sugar test rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or in the intravenous fluids.

B. OPIOID ANTAGONISTS—Naloxone, 0.4–2 mg intravenously or 2–4 mg by intranasal spray, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). **Note:** Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory.

C. FLUMAZENIL—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.* Flumazenil should **not** be given if the patient has coingested a potential convulsant drug, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. **Note:** Flumazenil has a short duration of effect (2–3 hours), and resedation requiring additional doses may occur.

HYPOTHERMIA

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure.

Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, beta-blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum or zinc phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

Treatment

Most hypotensive poisoned patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted (eg, as with massive diarrhea due to *Amanita phalloides* mushroom poisoning). Monitoring the central venous pressure (CVP) can help determine whether further fluid therapy is needed. If fluid therapy is not successful after adequate volume replacement, give dopamine or norepinephrine by intravenous infusion. Consider bedside cardiac ultrasound or pulmonary artery catheterization (or both) to assess CVP.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For beta-blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 unit/kg/h intravenously) euglycemic therapy may also be used (see the sections Beta-Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in some cases of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil. Intravenous methylene blue and extracorporeal membrane oxygenation (ECMO) have been employed in a few

refractory cases; ECMO may offer temporary hemodynamic stabilization while the offending drug is eliminated.

Heise CW et al. Two cases of refractory cardiogenic shock secondary to bupropion successfully treated with veno-arterial extracorporeal membrane oxygenation. *J Med Toxicol.* 2016 Sep;12(3):301–4. [PMID: 26856351]

Woodward C et al. High dose insulin therapy, an evidence-based approach to beta blocker/calcium channel blocker toxicity. *Daru.* 2014 Apr 8;22(1):36. [PMID: 24713415]

HYPERTENSION

► Assessment & Complications

Hypertension may be due to poisoning with amphetamines and synthetic stimulants, anticholinergics, cocaine, performance-enhancing products (containing caffeine, phenylephrine, ephedrine, or yohimbine), monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure greater than 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

► Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is higher than 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative (such as lorazepam, 2–3 mg intravenously) or an antipsychotic drug (eg, haloperidol or olanzapine). For persistent hypertension, administer phenolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add esmolol, 25–100 mcg/kg/min intravenously, or labetalol, 0.2–0.3 mg/kg intravenously. **Caution:** Do not give beta-blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed alpha-adrenergic stimulation.

Richards JR et al. Treatment of toxicity from amphetamines, related derivatives, and analogues: a systematic clinical review. *Drug Alcohol Depend.* 2015 May 1;150:1–13. [PMID: 25724076]

ARRHYTHMIAS

► Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

Table 38–1. Common toxins or drugs causing arrhythmias.¹

Arrhythmia	Common Causes
Sinus bradycardia	Beta-blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates
Atrioventricular block	Beta-blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium
Sinus tachycardia	Beta-agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants
Wide QRS complex	Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, bupropion, lamotrigine, diphenhydramine (severe overdose)
QT interval prolongation and torsades de pointes	Arsenic, class Ia and class III antiarrhythmics, citalopram, droperidol, lithium, methadone, pentamidine, sertraline, sotalol, and many other drugs ²
Ventricular premature beats and ventricular tachycardia	Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride, theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes).

¹Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia, hypomagnesemia).

²<https://crediblemeds.org/>

► Treatment

Hypoxia or electrolyte imbalance should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:** Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class Ia antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus infusion. **Caution:** Avoid class Ia antiarrhythmic agents (eg, procainamide, disopyramide) and amiodarone, which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies.

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

- Paratz ED et al. The cardiac complications of methamphetamines. *Heart Lung Circ*. 2016 Apr;25(4):325–32. [PMID: 26706652]

SEIZURES

Assessment & Complications

Seizures may be caused by many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, synthetic cannabinoids and cathinones, cocaine, isoniazid (INH), chlorinated insecticides, piperazines, tramadol, and theophylline. The onset of seizures may be delayed for up to 18–24 hours after extended-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is preferred over phenytoin or levetiracetam.) Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

- Chen HY et al. Treatment of drug-induced seizures. *Br J Clin Pharmacol*. 2016 Mar;81(3):412–9. [PMID: 26174744]

HYPERTHERMIA

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines and other synthetic stimulants (cathinones, piperazines), atropine and other anticholinergic drugs,

Table 38–2. Seizures related to toxins or drugs requiring special consideration.¹

Toxin or Drug	Comments
Methylenedioxymethamphetamine (MDMA; “Ecstasy”)	Seizures may also be due to hyponatremia or hyperthermia.
Isoniazid	Administer pyridoxine.
Lithium	May indicate need for hemodialysis.
Organophosphates	Administer pralidoxime (2-PAM) and atropine in addition to usual anticonvulsants.
Strychnine	“Seizures” are actually spinally mediated muscle spasms and usually require neuromuscular paralysis and mechanical ventilation.
Theophylline	Seizures indicate need for hemodialysis.
Tricyclic antidepressants	Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity.

¹See text for dosages.

cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (“serotonin syndrome”). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature higher than 40–41°C) can rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, acute kidney injury, and coagulopathy (see Chapter 37).

Treatment

Treat hyperthermia aggressively by removing the patient’s clothing, spraying the skin with tepid water, and high-volume fanning. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continued nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does

not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, or chlorpromazine, 25 mg intravenously or 50 mg intramuscularly, has been used to treat serotonin syndrome.

Walter E et al. Drug-induced hyperthermia in critical care. *J Intensive Care Soc*. 2015 Nov;16(4):306–11. [PMID: 28979436]

ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Be aware that some antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

Table 38–3. Some toxic agents for which there are specific antidotes.¹

Toxic Agent	Specific Antidote
Acetaminophen	<i>N</i> -Acetylcysteine
Anticholinergics (eg, atropine)	Physostigmine
Anticholinesterases (eg, organophosphate pesticides)	Atropine and pralidoxime (2-PAM)
Benzodiazepines	Flumazenil (rarely used) ²
Carbon monoxide	Oxygen (hyperbaric oxygen of uncertain benefit)
Cyanide	Sodium nitrite, sodium thiosulfate; hydroxocobalamin
Digitalis glycosides	Digoxin-specific Fab antibodies
Heavy metals (eg, lead, mercury, iron) and arsenic	Specific chelating agents
Isoniazid	Pyridoxine (vitamin B ₆)
Methanol, ethylene glycol	Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole)
Opioids	Naloxone, nalmefene
Snake venom	Specific antivenin
Sulfonylurea oral hypoglycemic drugs	Glucose, octreotide

¹See text for indications and dosages.

²May induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline, taking care to limit exposure to health care providers. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6 and 8. An amphoteric decontamination solution (Diphoterine, Prevor) is used in some countries for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons by induced emesis or gastric lavage was a routine part of emergency treatment for decades. However, prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying;

in some cases, when the interval after ingestion has been more than 1–2 hours and the ingested is non-life-threatening, even charcoal is withheld (eg, if the estimated benefit is outweighed by the potential risk of pulmonary aspiration of charcoal). Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours. In these cases, delayed gut decontamination may be indicated.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs.

B. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent

is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

C. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (fluid overload, electrolyte imbalance) usually outweighs its benefits. Some drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. To alkalinize the urine, add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4); (2) poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (including continuous venovenous hemodiafiltration and similar techniques) is of uncertain benefit for elimination of most poisons but has the advantage of gradual removal of the toxin and correction of any accompanying acidosis, and its use has been reported in the management of lithium intoxication.

Table 38–4. Recommended use of hemodialysis in poisoning.

Poison	Common Indications ¹
Carbamazepine	Seizures, severe cardiotoxicity; serum level > 60 mg/L
Ethylene glycol	Acidosis, serum level > 50 mg/dL
Lithium	Severe symptoms; level > 4–5 mEq/L, especially if kidney impairment Note: dialysis of uncertain value; consult with medical toxicologist
Methanol	Acidosis, serum level > 50 mg/dL
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, serum level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication)
Theophylline	Serum level > 90–100 mg/L (acute) or seizures and serum level
Valproic acid	Serum level > 900–1000 mg/L or deep coma, severe acidosis

¹See text for further discussion of indications.

CNS, central nervous system; CVVHD, continuous venovenous hemodialysis.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using repeat dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or else the resulting large stool volumes may lead to dehydration or hyponatremia.

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine, pseudoephedrine, synthetic cathinones and cannabinoids.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, gamma-hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and calculated osmol gap, electrolytes and anion gap, glucose, creatinine, blood urea nitrogen (BUN), creatine kinase, urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Quantitative serum acetaminophen and ethanol levels should be determined in all patients with drug overdoses.

A. Osmol Gap

The osmol gap (Table 38–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Other common poisons associated

Table 38–5. Use of the osmol gap in toxicology.

The osmol gap (Delta osm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

$$\text{Calculated osmolality} = 2[\text{Na}^+ (\text{mEq/L})] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$$

(osm)

$$\text{Delta osm} = \text{Measured osmolality} - \text{Calculated osmolality} = 0 \pm 10$$

Serum osmolality may be increased by contributions of exogenous substances such as alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration. Contact a medical toxicologist or poison control center for assistance in calculating and interpreting the osmol gap.

Adapted, with permission, from Stone CK, Humphries RL (editors): *Current Emergency Diagnosis & Treatment*, 5th ed. McGraw-Hill, 2004.

with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, propylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen, and salicylates. Massive acetaminophen overdose can cause early-onset anion gap metabolic acidosis.

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

C. Toxicology Laboratory Testing

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient because results usually do not return in time to influence clinical management. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

Many hospitals can perform a quick but limited urine screen for “drugs of abuse” (typically these screens include only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, methadone, oxycodone, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone, are often not detected by routine opiate immunoassays.

► Abdominal Imaging

A plain film (or CT scan) of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

► When to Refer

Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

► When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6- to 8-hour observation period.

Table 38–6. Specific quantitative levels and potential therapeutic interventions.¹

Drug or Toxin	Treatment
Acetaminophen	Specific antidote (<i>N</i> -acetylcysteine) based on serum level
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Carbamazepine	High level may indicate need for hemodialysis
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (eg, DigiFab) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols); serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both

¹Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

SELECTED POISONINGS

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (greater than 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as those who chronically abuse alcohol and patients taking INH, are at increased risk for developing hepatotoxicity. Hepatic toxicity may also occur after overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/day for several days. The amount of acetaminophen in US oral prescription combination products (eg, hydrocodone/acetaminophen) is limited by the FDA to no more than 325 mg per tablet.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, acute kidney injury, and death. Rarely, massive ingestion (eg, serum levels greater than 500–1000 mg/L [33–66 mmol/L]) can cause early onset of acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels which can make it difficult to interpret the nomogram. The nomogram is also not useful after chronic or staggered overdose.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

▲ Figure 38–1. Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. Patients with serum levels above the line after acute overdose should receive antidotal treatment. (Adapted, with permission, from Daly FF et al. Guidelines for the management of paracetamol poisoning in Australia and New Zealand—explanation and elaboration. A consensus statement from clinical toxicologists consulting to the Australasian poisons information centres. *Med J Austr*. 2008;188:296. © Copyright 2008 The Medical Journal of Australia. The Medical Journal of Australia does not accept responsibility for any errors in translation.)

B. Specific Treatment

If the serum or plasma acetaminophen level falls above the line on the nomogram (Figure 38–1), treatment with *N*-acetylcysteine is indicated; it can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to about 5% with water, juice, or soda. If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously. The conventional oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

The FDA-approved 21-hour intravenous regimen of acetylcysteine (Acetadote) calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with *N*-acetylcysteine is most effective if it is started within 8–10 hours after ingestion. Hemodialysis is rarely indicated, but might be needed in some patients with massive overdose.

ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

Treatment

A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do *not* give bicarbonate or other neutralizing agents, and do *not* induce vomiting. Some experts recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may also reveal the extent of injury. Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (**Caution:** Do not use calcium chloride.) Use of a Bier-block technique or intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Observe for and treat chemical pneumonitis or pulmonary edema.

ALKALIES

The strong alkalis are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalis cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

▶ Treatment

A. Ingestion

Dilute immediately with a glass of water. Do *not* induce emesis. Some gastroenterologists recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances, in order to remove residual material. However, others argue that passage of a gastric tube is contraindicated due to the risk of perforation or reexposure of the esophagus to the corrosive material from vomiting around the tube.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage; CT scanning may also aid in assessment. If a radiograph reveals ingested disk batteries lodged in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Amphoteric solutions may be more effective than water or saline and some are available in Europe (Diphoterine, Prevor). Check pH with pH test paper and repeat irrigation for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist for further treatment.

Brent J. Water-based solutions are the best decontaminating fluids for dermal corrosive exposures: a mini review. *Clin Toxicol* (Phila). 2013 Sep–Oct;51(8):731–6. [PMID: 24003912]

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely abused for their euphorogenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine (“crystal meth,” “crank”), MDMA (“Ecstasy”), ephedrine (“herbal ecstasy”), and methcathinone (“cat” or “khat”). Methcathinone derivatives and related synthetic chemicals such as methylenedioxypyrrovalerone (MDPV) have become popular drugs of abuse and are often sold as purported “bath salts.” Amphetamine-like reactions have also been reported after use of synthetic cannabinoids (eg, “Spice” and “K2”). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see also Theophylline & Caffeine section).

▶ Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction; chronic use may cause cardiomyopathy. Ischemic colitis has been reported. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines or the cocaine metabolite benzoylecgonine in the urine. Note that many drugs can give false-positive results on the immunoassay for amphetamines, and most synthetic stimulants do not react with the immunoassay, giving false-negative results.

▶ Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter. Rapidly lower the body temperature in patients who are hyperthermic (temperature higher than 39–40°C). Give intravenous fluids to prevent myoglobinuric kidney injury in patients who have rhabdomyolysis.

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or nitroprusside, or a combined alpha- and beta-adrenergic blocker such as labetalol (10–20 mg intravenously). Do *not* administer a pure beta-blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed alpha-adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting beta-blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above. Treat hyponatremia as outlined in Chapter 21.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides, the so-called superwarfarins such as brodifacoum, difenacoum, and related compounds) inhibit the normal clotting system by blocking hepatic synthesis of vitamin K–dependent clotting factors. After ingestion of “superwarfarins,” inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose. Newer oral anticoagulants include the direct thrombin inhibitor dabigatran and the factor Xa inhibitors rivaroxaban, apixiban, and edoxaban. Some of these, especially dabigatran, are largely eliminated by the kidney and may accumulate in patients with kidney dysfunction.

Excessive anticoagulation may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces.

Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normalized ratio, INR). The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after overdose of warfarin or “superwarfarins.” **Note:** The newer oral anticoagulants (dabigatran, rivaroxaban, apixiban, and edoxaban) do not predictably alter the prothrombin time; however, a normal INR suggests no significant toxicity.

If the patient has ingested an acute overdose, administer activated charcoal.

B. Specific Treatment

1. Warfarin—*In cases of warfarin and “superwarfarin” overdose, do not treat prophylactically with vitamin K—wait for evidence of anticoagulation (elevated prothrombin time).* See Table 14–21 for the management of INR above therapeutic range. Doses as high as 200 mg/day have been required after ingestion of “superwarfarins.” Give fresh-frozen plasma, prothrombin complex concentrate, or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time. If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

2. Direct-acting oral anticoagulants—Vitamin K does not reverse the anticoagulant effects of the direct-acting oral anticoagulants (dabigatran, rivaroxaban, apixiban, and edoxaban). **Idarucizumab** has been approved by the FDA for reversal of the thrombin inhibitor dabigatran; **andexanet** remains under investigation for reversal of the factor Xa inhibitors (apixaban, edoxaban and rivaroxaban). The efficacy of fresh-frozen plasma and clotting factor concentrates is uncertain.

ANTICONSULSANTS

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders and some are also used for treatment of mood disorders or pain.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine intoxication causes drowsiness, stupor and, with high levels, atrioventricular block, coma, and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels over 20 mg/L (85 mcmmol/L), although severe poisoning is usually associated with concentrations greater than 30–40 mg/L (127–169 mcmmol/L). Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hyponatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants **gabapentin**, **levetiracetam**, **vigabatrin**, and **zonisamide** generally cause somnolence, confusion, and dizziness; there is one case report of hypotension and bradycardia after a large overdose of levetiracetam. **Felbamate** can cause crystalluria and kidney injury after overdose and may cause idiosyncratic aplastic anemia with therapeutic use. **Lamotrigine**, **topiramate**, and **tiagabine** have been reported to cause seizures after overdose; lamotrigine has sodium-channel blocking properties and may cause QRS prolongation and heart block.

▶ Treatment

A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube. For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation. Combined multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

B. Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid–induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels greater than 60 mg/L [254 mcmmol/L] or valproic acid levels greater than 800 mg/L [5544 mcmmol/L]).

ANTIPSYCHOTIC DRUGS

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antipsychotic agents, and sometimes as antiemetics and potentiators of analgesic and hypnotic drugs.

Therapeutic doses of conventional phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, lurasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25).

▶ Treatment

A. Emergency and Supportive Measures

Administer activated charcoal for large or recent ingestions. For severe hypotension, treatment with intravenous fluids and vasopressor agents may be necessary. Treat hyperthermia as outlined. Maintain cardiac monitoring.

B. Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants. Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle rigidity but is not a true antidote. For severe hyperthermia, rapid neuromuscular paralysis is preferred.

ARSENIC

Arsenic is found in some pesticides and industrial chemicals and is used as a chemotherapeutic agent. Chronic arsenic poisoning has been associated with contaminated aquifers used for drinking water. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Cancers of the lung, bladder, and skin have been reported. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

Treatment

A. Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage. Activated charcoal is of uncertain benefit because it binds arsenic poorly. Administer intravenous fluids to replace losses due to vomiting and diarrhea.

B. Antidote

For patients with severe acute intoxication, administer a chelating agent. The preferred drug is 2,3-dimercaptopropanesulfonic acid (DMPS, Unithiol) (3–5 mg/kg intravenously every 4 hours); although there is no FDA-approved commercial formulation of DMPS in the United States, it can be obtained from some compounding pharmacies. An alternative parenteral chelator is dimercaprol (British anti-Lewisite, BAL), which comes as a 10% solution in peanut oil, and is given 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. When gastrointestinal symptoms allow, switch to the oral chelator succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice regarding chelation.

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. Symptoms of toxicity include dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. Physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive diphenhydramine overdose may mimic tricyclic antidepressant cardiotoxic poisoning.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal. External cooling and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures.

B. Specific Treatment

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. **Caution:** Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and the drug should be avoided in patients with evidence of cardiotoxic effects from tricyclic antidepressants or other sodium channel blockers.

BETA-ADRENERGIC BLOCKERS

There are a wide variety of beta-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–7). The most toxic beta-blocker is propranolol, which not only blocks beta-1 and beta-2 adrenoceptors but also has direct membrane-depressant and central nervous system effects.

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to

conventional therapy with beta-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include beta-blockers.

▶ Treatment

A. Emergency and Supportive Measures

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary.

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal.

B. Specific Treatment

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by beta-blockade. High-dose insulin (0.5–1 unit/kg/h intravenously) along with glucose supplementation has been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose.

Cole JB et al. A blinded, randomized, controlled trial of three doses of high-dose insulin in poison-induced cardiogenic shock. *Clin Toxicol (Phila)*. 2013 May;51(4):201–7. [PMID: 23530460]

Heise CW et al. Massive atenolol, lisinopril, and chlorthalidone overdose treated with endoscopic decontamination, hemodialysis, Impella percutaneous left ventricular assist device, and ECMO. *J Med Toxicol*. 2015 Mar;11(1):110–4. [PMID: 25146229]

CALCIUM CHANNEL BLOCKERS

In therapeutic doses, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

▶ Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal. In addition, whole bowel irrigation should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

Treat symptomatic bradycardia with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker. For hypotension, give calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to as much as twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. High doses of insulin (0.5–1 unit/kg intravenous bolus followed by 0.5–1 unit/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial, but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and case reports of calcium channel blocker poisoning. Methylene blue (1–2 mg/kg) was reported to reverse refractory shock due to profound vasodilation in a patient with amlodipine poisoning. ECMO has been recommended for refractory shock.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater, generator, or other appliance. Some carbon monoxide can be generated during degradation of anesthetic gases. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

▶ Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and

seizures are common with levels greater than 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A specialized pulse oximetry device, the Masimo pulse CO-oximeter, is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CHEMICAL WARFARE: NERVE AGENTS

Nerve agents used in chemical warfare work by cholinesterase inhibition and are most commonly organophosphorus compounds. Agents such as **tabun** (GA), **sarin** (GB), **soman** (GD), and **VX** are similar to insecticides such as malathion

but are vastly more potent. They may be inhaled or absorbed through the skin. Systemic effects due to unopposed action of acetylcholine include miosis, salivation, abdominal cramps, diarrhea, and muscle paralysis producing respiratory arrest. Inhalation also produces severe bronchoconstriction and copious nasal and tracheobronchial secretions.

Treatment

A. Emergency and Supportive Measures

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

B. Specific Treatment

Give atropine in an initial dose of 2 mg intravenously and repeat as needed to reverse signs of acetylcholine excess. (Some victims have required several hundred milligrams.) Treat also with the cholinesterase-reactivating agent pralidoxime, 1–2 g intravenously initially followed by an infusion at a rate of 200–400 mg/h.

Agency for Toxic Substances and Disease Registry. Toxic Substances Portal: Medical Management Guidelines for Nerve Agents: Tabun (GA); Sarin (GB); Soman (GD); and VX. October 21, 2014. <https://www.atsdr.cdc.gov/mmg/mmg.asp?id=523&tid=93>

Candiotti K. A primer on nerve agents: what the emergency responder, anesthesiologist, and intensivist needs to know. *Can J Anaesth*. 2017 Oct;64(10):1059–70. [PMID: 28766156]

CHEMICAL WARFARE: RICIN

Ricin is a naturally occurring toxin found in minute quantities in the castor bean (*Ricinus communis*). It can cause toxicity if castor beans are thoroughly chewed or blenderized, although the quantity of ricin is small and it is poorly absorbed from the gastrointestinal tract, so symptoms following castor bean ingestion are usually limited to diarrhea and abdominal pain. Less commonly, severe gastroenteritis can lead to volume depletion and advanced chronic kidney disease. On the other hand, purified ricin is extremely toxic if administered parenterally: the LD₅₀ for injected ricin in animals is as low as 0.1 mcg/kg. A fatal case of suspected ricin poisoning by homicidal injection of an estimated 0.28 mg of ricin was associated with diffuse organ damage and death from cardiac failure after 2 days. Inhalation of ricin powder has not been reported in humans, but animal studies suggest it could cause hemorrhagic tracheobronchitis and pneumonia.

Treatment

A. Emergency and Supportive Measures

After suspected ricin inhalation or exposure to powdered ricin, remove clothing and wash skin with water. Personnel

caring for such patients should wear protective respiratory gear, clothing, and gloves.

B. Specific Treatment

There is no known antidote or other specific treatment. A vaccine has been developed and has been granted an Orphan Drug designation by the FDA. Provide supportive care for volume loss due to gastroenteritis and cardiac and respiratory support as needed.

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyldopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a result of peripheral alpha-adrenergic effects in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine and apraclonidine are used as ophthalmic preparations for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

► Treatment

A. Emergency and Supportive Measures

Give activated charcoal. Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

B. Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unpredictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

Isbister GK et al. Adult clonidine overdose: prolonged bradycardia and central nervous system depression, but not severe toxicity. *Clin Toxicol (Phila)*. 2017 Mar;55(3):187–92. [PMID: 28107093]

COCAINE

See Amphetamines & Cocaine.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

► Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (greater than 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

► Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal. Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, there are two available cyanide antidote regimens. The conventional cyanide antidote package (Nithiodote) contains sodium nitrite (to induce methemoglobinemia, which binds free cyanide) and sodium thiosulfate (to promote conversion of cyanide to the less toxic

thiocyanate). Administer 3% sodium nitrite solution, 10 mL intravenously followed by 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g). **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin.

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose of hydroxocobalamin is 5 g intravenously (children's dose is 70 mg/kg). **Note:** Hydroxocobalamin causes red discoloration of skin and body fluids that may last several days and can interfere with some laboratory tests.

DIETARY SUPPLEMENTS & HERBAL PRODUCTS

Unlike prescription and over-the-counter pharmaceuticals, dietary supplements do not require FDA approval, do not undergo the same premarketing evaluation of safety and efficacy as drugs, and purveyors may or may not adhere to good manufacturing practices and quality control standards. Supplements may cause illness as a result of intrinsic toxicity, misidentification or mislabeling, drug-herb reactions, or intentional adulteration with pharmaceuticals. If you suspect a dietary supplement or herbal product may be the cause of an otherwise unexplained illness, contact the

FDA (1-888-463-6332) or the regional poison control center (1-800-222-1222), or consult one of the following online databases: and <http://www.fda.gov/food/dietarysupplements/default.htm>.

Table 38–7 lists selected examples of clinical toxicity from some of these products.

- Avigan MI et al. Scientific and regulatory perspectives in herbal and dietary supplement associated hepatotoxicity in the United States. *Int J Mol Sci.* 2016 Mar 3;17(3):331. [PMID: 26950122]
- Cohen PA et al. Presence of banned drugs in dietary supplements following FDA recalls. *JAMA.* 2014 Oct 22–29; 312(16):1691–3. [PMID: 25335153]

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides paralyze the Na^+/K^+ -ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. A number of plants (eg, oleander, foxglove, lily-of-the-valley) contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdose, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be

Table 38–7. Examples of potential toxicity associated with some dietary supplements and herbal medicines.

Product	Common Use	Possible Toxicity
Azarcon (Greta)	Mexican folk remedy for abdominal pain, colic	Contains lead
Comfrey	Gastric upset, diarrhea	Contains pyrrolizidine alkaloids, can cause hepatic veno-occlusive disease
Creatine	Athletic performance enhancement	Nausea, diarrhea, abdominal cramps; elevated serum creatinine
Ginkgo	Memory improvement, tinnitus	Antiplatelet effects, hemorrhage; abdominal pain, diarrhea
Ginseng	Immune system; stress	Decreased glucose; increased cortisol
Guarana	Athletic performance enhancement, appetite suppression	Contains caffeine: can cause tremor, tachycardia, vomiting
Kava	Anxiety, insomnia	Drowsiness, hepatitis, skin rash
Ma huang	Stimulant; athletic performance enhancement	Contains ephedrine: anxiety, insomnia, hypertension, tachycardia, seizures
Spirulina	Body building	Niacin-like flushing reaction
Yohimbine	Sexual enhancement	Hallucinations, hypertension, tachycardia
Zinc	Cold/flu symptoms	Nausea, oral irritation, anosmia

Adapted, with permission, from Table II-30 by Haller C in "Herbal and Alternative Products," In: Olson KR (ed.) *Poisoning & Drug Overdose*, 6th edition. McGraw Hill, 2011.

hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal. Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

B. Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; DigiFab). Estimation of the dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration, as described below. More effective binding of digoxin may be achieved if the dose is given partly as a bolus and the remainder as an infusion over a few hours.

1. From the ingested dose—Number of vials = approximately $1.5\text{--}2 \times$ ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) $\times$ body weight (kg) $\times 10^{-2}$. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels may be falsely high for several hours before tissue distribution is complete, and overestimation of the DigiFab dose is likely.

3. Empiric dosing—Empiric titration of DigiFab may be used if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) favors retaining a residual level of digitalis activity. Start with one or two vials and reassess the patient's clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is entirely based on response to empiric dosing.

Note: After administration of digoxin-specific Fab antibody fragments, serum digoxin levels may be falsely elevated depending on the assay technique.

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlorthalidone, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem and zaleplon, and the muscle relaxant carisoprodol. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

► Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels over 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected. Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in 0.2–0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** *Flumazenil should rarely be used because it may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose.* If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

GAMMA-HYDROXYBUTYRATE (GHB)

GHB is a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (“date-rape” drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and gamma-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines; baclofen has also been used.

HYPOGLYCEMIC DRUGS

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, α -glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), and peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 27). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in patients with impaired kidney function or after

intentional drug overdose. Table 27–5 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Table 27–6 the extent and duration of various types of insulins.

Clinical Findings

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a “depot” effect. Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given.

Treatment

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 mL intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose greater than 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

Consider hemodialysis for patients with metformin overdose accompanied by severe lactic acidosis (lactate greater than 20 mmol/L or pH < 7.0).

ISONIAZID

INH is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain gamma-aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.

Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of

proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

► Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote.

Administer activated charcoal after large recent ingestion, but with caution because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

LEAD

Lead is used in a variety of industrial and commercial products, such as firearms ammunition, storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

► Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions.

Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels above 5 mcg/dL warrant public health investigation. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels greater than 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

► Treatment

A. Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation, endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level over 60 mcg/dL (or three successive monthly levels greater than 50 mcg/dL) or construction workers with any single blood lead level above 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (1-800-222-1222) should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 mcg/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels greater than 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m²/kg/day (approximately 50 mg/kg/day) in four to six divided doses or as a continuous intravenous infusion. Most clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LITHIUM

Lithium is widely used for the treatment of bipolar depression and other psychiatric disorders. The only normal route of lithium elimination is via the kidney, so patients with acute or chronic kidney disorders are at risk for accumulation of lithium resulting in gradual onset (chronic) toxicity. Intoxication resulting from chronic accidental overmedication or kidney impairment is more common and usually more severe than that seen after acute oral overdose.

Clinical Findings

Mild to moderate toxicity causes lethargy, confusion, tremor, ataxia, and slurred speech. This may progress to myoclonic jerking, delirium, coma, and convulsions. Recovery may be slow and incomplete following severe intoxication. Laboratory studies in patients with chronic intoxication often reveal an elevated serum creatinine and an elevated BUN/creatinine ratio due to underlying volume contraction. The white blood cell count is often elevated. ECG findings include T-wave flattening or inversion, and sometimes bradycardia or sinus node arrest. Nephrogenic diabetes insipidus can occur with overdose or with therapeutic doses.

Lithium levels may be difficult to interpret. Lithium has a low toxic: therapeutic ratio and chronic intoxication can be seen with levels only slightly above the therapeutic range (0.8–1.2 mEq/L). In contrast, patients with acute ingestion may have transiently very high levels (up to 10 mEq/L reported) without any symptoms before the lithium fully distributes into tissues. **Note:** Falsely high lithium levels (as high as 6–8 mEq/L) can be measured if a green-top blood specimen tube (containing lithium heparin) is used for blood collection.

Treatment

After acute oral overdose, consider gastric lavage or whole bowel irrigation to prevent systemic absorption (**Note:** lithium is not adsorbed by activated charcoal). In all

patients, evaluate kidney function and volume status, and give intravenous saline-containing fluids as needed. Monitor serum lithium levels and seek assistance with their interpretation and the need for dialysis from a medical toxicologist or regional poison control center (1-800-222-1222). Consider hemodialysis if the patient is markedly symptomatic or if the serum level exceeds 4–5 mEq/L, especially if kidney function is impaired. Continuous renal replacement therapy may be an effective alternative to hemodialysis.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, “chemo,” etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias. Other drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists, *Salvia divinorum*, synthetic tryptamines, and phenylethylamines, and mephedrone and related cathinone derivatives. See www.erowid.org for very thorough descriptions of a variety of hallucinogenic substances.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with beta-blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

MERCURY

Mercury poisoning may occur by ingestion of inorganic mercuric salts, organic mercury compounds, or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from highly contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects. Nearly all fish have some traces of mercury contamination; the US Environmental Protection Agency (EPA) advises consumers to avoid swordfish, shark, king mackerel, and tilefish because they contain higher levels. Fish and shellfish that are generally low in mercury content include shrimp, canned light tuna (not albacore “white” tuna), salmon, pollock, and catfish. Dental fillings composed of mercury amalgam pose a very small risk of chronic mercury poisoning and their removal is rarely justified. Some imported skin lightening creams contain toxic quantities of mercury.

▶ Treatment

A. Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage and administer activated charcoal. For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Unithiol

(DMPS) is a chelator that can be given orally or parenterally but is not commonly available in the United States; it can be obtained from some compounding pharmacies. Maintain urinary output. Treat oliguria and anuria if they occur.

B. Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, although some authors recommend a trial of succimer or unithiol (contact a regional poison center or medical toxicologist for advice).

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerine in various liquid medications (cough syrup, teething medicine, acetaminophen), causing numerous deaths in Haiti, Panama, and Nigeria.

▶ Clinical Findings

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and acute kidney injury. **Note:** Point-of-care analytical devices common used in the emergency department may falsely measure glycolic acid (a toxic metabolite of ethylene glycol) as lactic acid.

▶ Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a

nasogastric tube. Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propyl (an herbicide), nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the

“chocolate brown” color of methemoglobin, but they have normal PO₂ results on arterial blood gas determinations. Conventional pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. (A newer pulse oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal. Repeat-dose activated charcoal may enhance dapsone elimination.

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides* and related species, which contain potent cytotoxins (amatoxins). Ingestion of even a portion of one amatoxin-containing mushroom may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings

Amatoxin-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal

cramps, vomiting and profuse diarrhea, followed in 1–2 days by acute kidney injury, hepatic necrosis, and hepatic encephalopathy. Cooking the mushrooms does not prevent poisoning.

Monomethylhydrazine poisoning (*Gyromitra* and *Helvella* species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours.

▶ Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 8–12 hours or more before symptoms occur and patients seek medical attention. However, activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom. Administer intravenous fluids liberally to replace massive losses from vomiting and diarrhea; monitor central venous pressure, urinary output, and kidney function tests to help guide volume replacement.

B. Specific Treatment

A variety of purported antidotes (eg, thiocetic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe, but is currently commercially available only in the United States as an oral nutritional supplement. The European intravenous product (Legalon-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

▶ Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone may cause QT interval prolongation and torsades de pointes. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. Propoxyphene prolongs the QRS interval and may cause seizures; it is no longer available in the United States. Wound botulism has been associated with skin-popping, especially involving “black tar” heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology “opiate” screening.

▶ Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal for recent large ingestions.

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.2–2 mg intravenously and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). **Caution:** The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene and are well absorbed through intact skin. Most chemical warfare “nerve agents” (such as GA [tabun], GB [sarin], GD [soman] and VX) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube followed by administration of activated charcoal. If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute

hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a more specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

Treatment

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized crackles or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

SALICYLATES

Salicylates (aspirin, methyl salicylate, bismuth subsalicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. (A normal anion gap sometimes occurs due to salicylate interference with the chemistry analyzer, falsely raising the measured chloride.) Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. Central nervous system intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by

measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L or 7.2 mmol/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL (4.3–5 mmol/L). The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal orally. Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin. The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation. Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall due to hypercarbia during the apneic period.

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, greater than 100–120 mg/dL [1000–1200 mg/L or 7.2–8.6 mmol/L] after acute overdose or greater than 60–70 mg/dL [600–700 mg/L or 4.3–5 mmol/L] with subacute or chronic intoxication).

Table 38–8. Common seafood poisonings.

Type of Poisoning	Mechanism	Clinical Presentation
Ciguatera	Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.	1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.
Paralytic shellfish poisoning	Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–8. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

► Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally.

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H₂-blocker cimetidine, 300 mg intravenously, are usually effective.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

► Treatment

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours have been recommended, but many clinicians give additional doses only if needed. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 1–2 vials of specific antivenom as soon as possible. **Note:** Pfizer/Wyeth no longer makes coral snake antivenom in the United States and remaining supplies are dwindling. To locate antisera for this or exotic snakes, call a regional poison control center (1-800-222-1222).

SPIDER BITES & SCORPION STINGS

The toxin of most species of spiders in the United States causes only local pain, redness, and swelling. That of the more venomous black widow spiders (*Latrodectus mactans*) causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare).

Stings by most scorpions in the United States cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

► Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral opioids or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may transiently relieve muscle rigidity, though its effectiveness is unproven.

Latrodectus antivenom is possibly more effective, but because of concerns about acute hypersensitivity reactions (horse serum–derived), it is often reserved for very young or elderly patients or those who do not respond promptly to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproved value.

C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. An FDA-approved specific antivenom is available for *Centruroides* stings.

THEOPHYLLINE & CAFFEINE

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine in energy drinks or herbal or dietary supplement products can produce similar toxicity.

► Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum

levels greater than 100 mg/L (555 mcmol/L). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 mcmol/L]) in patients with chronic intoxication. Serum caffeine levels are not routinely available in clinical practice, but in a study of 51 fatal cases the median level was 180 mg/L (range 33–567 mg/L).

Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal. Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations.

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, greater than 100 mg/L [555 mcmol/L] after acute overdose or greater than 60 mg/L [333 mcmol/L] with chronic intoxication).

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive beta-adrenergic stimulation—may respond to beta-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer-generation antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and, with the exception of bupropion, do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome.

Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils,

▲ **Figure 38-2.** Cardiac arrhythmias resulting from tricyclic antidepressant overdose. **A:** Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). **B and C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998. Copyright © Elsevier.)

tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (greater than 0.12 s; Figure 38-2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval and torsades de pointes have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity.

Administer activated charcoal and consider gastric lavage after recent large ingestions. All of these drugs have large volumes of distribution and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has reportedly responded to intravenous lipid emulsion (Intralipid), 1.5 mL/kg repeated one or two times if needed. Plasma exchange using albumin has been reported successful in a few cases.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

INTRODUCTION TO CANCER

Patricia A. Cornett, MD

Tiffany O. Dea, PharmD

► Etiology

Cancer is the second most common cause of death in the United States. In 2017, an estimated 1,688,780 cases of cancer were diagnosed, and 600,920 persons died of cancer. Based on current statistics, almost 40% of Americans will be diagnosed with cancer at some point during their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the death rates from cancer are decreasing. Compared to the 1991 cancer death rate of 215.1 per 100,000 population, the 2012 rate of 171.2 per 100,000 represents a 20% reduction in its death rate. Importantly, death rates have declined in the four most common cancer types (lung, colon-rectum, breast, and prostate). The largest declines in death rates in women have been in non-Hodgkin lymphoma and colorectal cancer and in men, in prostate and stomach cancers. Reductions in cancer mortality reflect successful implementation of a broad strategy of prevention, detection, and treatment. Due to these improvements, the number of cancer survivors is increasing. In 2015, an estimated 14.5 million people were alive in whom cancer had been previously diagnosed; that number is projected to grow to 18.9 million in 2024.

► Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; at least 30% of all cancer deaths in the United States are directly linked to tobacco. In 2014, an estimated 167,133 cancer deaths in the United States could be directly attributed to tobacco. Clear evidence links tobacco use to at least 15 cancers. The most dramatic link is with lung cancer; 80% of lung cancer cases occur in smokers. Remarkably, almost 10% of long-term survivors of a

tobacco-related cancer continue to use tobacco products, increasing their risk of yet another cancer.

Tobacco cessation directed toward the individual should start with clinician counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, or lozenges; and prescription medication with bupropion or varenicline (see Chapter 1).

On a societal level, state or local laws regulating tobacco use in restaurants, workplace, and other public places have resulted in declines in tobacco use. Counter-marketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key targets of these messages are children; 80% of smokers start by age 18.

There are encouraging signs of success with tobacco control. The prevalence of smoking for US adults based on the 2016 National Health Interview Survey is 16.0%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females.

For those Americans who do not use tobacco, the most modifiable risk factors would be nutrition and physical activity. Prudent recommendations to reduce cancer risk are to (1) avoid tobacco; (2) be physically active; (3) maintain a healthy weight; (4) consume a diet rich in fruits, vegetables, and whole grains; (5) lower consumption of saturated and trans dietary fats; (6) limit alcohol use; and (7) avoid excess sun exposure.

Another modifiable cancer risk factor is radiation from radiographic studies. A 2009 study reported that the use of computed tomography (CT) in diagnostic algorithms exposes individuals to significant radiation doses that may increase their lifetime risk of cancer. Both standardization of CT radiation doses and limiting testing have been important steps in minimizing this risk. The American Society of Hematology and American Society of Clinical Oncology have guidelines, inspired by the American Board of Internal Medicine Foundation's "Choosing Wisely" campaign, for limiting radiographic testing, particularly when used in surveillance for treated cancer patients.

Table 39–1. Estimated 10 most common cancer cases in the United States in males and females (all races).

Rank	Males	Females
	Total Cases = 836,150 (percent)	Total Cases = 852,630 (percent)
1	Prostate (19)	Breast (30)
2	Lung and bronchus (14)	Lung and bronchus (12)
3	Colon and rectum (9)	Colon and rectum (8)
4	Urinary bladder (7)	Uterine corpus (7)
5	Melanoma (6)	Thyroid (5)
6	Kidney and renal pelvis (5)	Melanoma (4)
7	Non-Hodgkin lymphoma (5)	Non-Hodgkin lymphoma (4)
8	Leukemia (4)	Leukemia (3)
9	Oral cavity and pharynx (4)	Pancreas (3)
10	Liver and intrahepatic bile duct (3)	Kidney and renal pelvis (3)

Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see <https://www.cancerstaging.org>). Rules for staging for individual cancers are established and published by the American Joint Committee on Cancer (AJCC). The elements used for staging are tumor location, size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and absence or presence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas.

Other characteristics of cancers, not reflected in the TNM stage, may be used to indicate prognosis and guide treatment. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Cancer specimens should also be sent for targeted molecular diagnostic testing, when appropriate. Examples include testing for *HER2* in breast and gastric cancer; *K-ras* and *BRAF* mutations in colorectal cancer; *BRAF* mutations in melanoma; epidermal growth factor receptor (EGFR), *K-ras* mutations, and the *ALK* fusion gene in lung cancer; and programmed death-ligand 1 (PD-L1) expression testing in a variety of cancers.

Treatment

See Primary Cancer Treatment section below. Table 39–2 outlines treatment choices by cancer type for those responsive to systemic agents, and Table 39–3 provides a listing of common chemotherapeutic agents.

Table 39–2. Treatment choices for cancers responsive to systemic agents.

Diagnosis	Current Treatment of Choice	Other Treatments
Acute lymphoblastic leukemia (ALL)	Induction combination chemotherapy: Vincristine, prednisone, daunorubicin, asparaginase, intrathecal methotrexate Consolidation combination chemotherapy: Cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) alternated with cytarabine, methotrexate Maintenance chemotherapy: Methotrexate, 6-mercaptopurine Philadelphia chromosome–positive ALL: Add imatinib or dasatinib or nilotinib or ponatinib to above regimen	Blinatumomab, inotuzumab ozogamicin, tisagenlecleucel, liposomal vincristine, clofarabine, nelarabine (T-cell ALL), nilotinib, bosutinib, ponatinib (Philadelphia chromosome–positive ALL), autologous or allogeneic transplantation for high risk or at relapse
Acute myeloid leukemia (AML)	Combination chemotherapy: Cytarabine, daunorubicin or Cytarabine, idarubicin or Cytarabine, daunomycin, cladribine	Mitoxantrone, doxorubicin, fludarabine, 5-azacytidine, decitabine, clofarabine, midostaurin (FLT3 mutation +)
Chronic myeloid leukemia (CML)	Nilotinib or Dasatinib or Imatinib mesylate	Ponatinib, bosutinib, omacetaxine, allogeneic bone marrow transplantation
Chronic lymphocytic leukemia (CLL)	Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR) or Bendamustine, rituximab Single-agent chemotherapy: Ibrutinib or obinutuzumab or ofatumumab or chlorambucil	Alemtuzumab, idelalisib, venetoclax, lenalidomide, pentostatin, cladribine, cyclophosphamide, vincristine, doxorubicin, prednisone

(continued)

Table 39–2. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Hairy cell leukemia	Cladribine (2-chlorodeoxyadenosine)	Pentostatin, rituximab, interferon-alpha, vemurafenib, ibrutinib
Hodgkin lymphoma (stages III and IV)	Combination chemotherapy: Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD), or Doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, prednisone (Stanford V), or Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone (BEACOPP)	Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP), or Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP), or Ifosfamide, carboplatin, etoposide (ICE), or Mesna, ifosfamide, mitoxantrone, etoposide (MIME); stem cell transplantation for high risk or first relapse Brentuximab vedotin, nivolumab, pembrolizumab, bendamustine, everolimus
Non-Hodgkin lymphoma (intermediate and high grade)	Combination chemotherapy: Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab (CHOP-R), or Etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, rituximab (Dose-adjusted R-EPOCH) (for double rearrangements)	Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP), or Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP), or Ifosfamide, carboplatin, etoposide (ICE), or Mesna, ifosfamide, mitoxantrone, etoposide (MIME); transplantation for high risk or first relapse
Non-Hodgkin lymphoma (low grade)	Combination chemotherapy: Bendamustine, rituximab, or Cyclophosphamide, vincristine, doxorubicin, prednisone, rituximab (CHOP-R), or Cyclophosphamide, vincristine, prednisone, rituximab (CVP-R), or Lenalidomide, rituximab	Chlorambucil, fludarabine, copanlisib, obinutuzumab, ⁹⁰ Y ibritumomab tiuxetan, bendamustine, lenalidomide, idelalisib, ibrutinib, belinostat (T-cell lymphoma), autologous or allogeneic transplantation
Plasma cell myeloma (formerly multiple myeloma)	Combination chemotherapy (transplant candidates): Bortezomib, dexamethasone, cyclophosphamide, or Bortezomib, dexamethasone, lenalidomide, or Dexamethasone, lenalidomide, or Ixazomib/lenalidomide/dexamethasone, or Carfilzomib/lenalidomide/dexamethasone Followed by autologous or miniallogeneic stem cell transplantation Combination chemotherapy (non-transplant candidates): Lenalidomide, dexamethasone, or Melphalan, prednisone, bortezomib, or Melphalan, prednisone, lenalidomide, or Melphalan, prednisone, thalidomide	Liposomal doxorubicin, pomalidomide, panobinostat, elotuzumab, daratumumab
Waldenström macroglobulinemia	Plasmapheresis alone or followed by combination chemotherapy: Bortezomib with or without rituximab, or Thalidomide with or without rituximab, or Rituximab, cyclophosphamide, prednisone, or Carfilzomib, rituximab, dexamethasone or ibrutinib	Cladribine, ofatumumab, chlorambucil, bendamustine, alemtuzumab, everolimus, autologous bone marrow transplantation
Polycythemia vera	Phlebotomy, hydroxyurea, aspirin	Ruxolitinib, radiophosphorus ³² P, interferon-alpha
Non–small cell lung cancer	Combination chemotherapy: Cisplatin, vinorelbine, or Cisplatin, etoposide, or Paclitaxel, carboplatin, or Cisplatin, gemcitabine (squamous histology) Cisplatin, pemetrexed (nonsquamous histology) All regimens with or without bevacizumab Erlotinib, gefitinib, osimertinib or afatinib (<i>EGFR</i> mutation positive), or Crizotinib, alectinib, ceritinib, brigatinib (<i>ALK</i> mutation positive) Certitinib, crizotinib (<i>ROS1</i> rearrangement) Dabrafenib/trametinib (<i>BRAF</i> V600F mutation) Pembrolizumab (PD-L1 expression)	Docetaxel, cetuximab, pembrolizumab, nivolumab, atezolizumab, osimertinib, necitumumab, ramucirumab, cabozantinib (<i>RET</i> rearrangement), trastuzumab, afatinib (<i>HER2</i> mutation positive), alectinib, brigatinib, ceritinib (<i>ALK</i> rearrangement)

(continued)

Table 39–2. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Small cell lung cancer	Combination chemotherapy: Cisplatin, etoposide, or Carboplatin, etoposide, or Cisplatin, irinotecan	Irinotecan, cyclophosphamide, doxorubicin, vincristine, topotecan, gemcitabine, paclitaxel, bendamustine, temozolomide, nivolumab, ipilimumab
Mesothelioma	Combination chemotherapy: Cisplatin, pemetrexed, or Carboplatin, pemetrexed, or Gemcitabine, cisplatin	Vinorelbine, nivolumab with or without ipilimumab, pembrolizumab
Head and neck cancer	Combination chemotherapy: Cisplatin, fluorouracil, or Paclitaxel, carboplatin, or Docetaxel, cisplatin, fluorouracil, or Cisplatin or cetuximab with radiation therapy	Methotrexate, afatinib, pembrolizumab, nivolumab
Esophageal and esophagogastric junction cancer	Combination chemotherapy: Cisplatin, fluorouracil, or Paclitaxel, carboplatin, or Oxaliplatin, fluorouracil or Docetaxel, cisplatin, fluorouracil	Irinotecan, oxaliplatin, capecitabine, epirubicin, docetaxel, trastuzumab or ramucirumab (esophagogastric junction cancer), pembrolizumab
Uterine cancer	Hormone therapy: Progestins, tamoxifen, aromatase inhibitors, fulvestrant or Combination chemotherapy: Cisplatin, doxorubicin, or Docetaxel, carboplatin, or Carboplatin, paclitaxel	Liposomal doxorubicin, bevacizumab, topotecan, temsirolimus, pembrolizumab
Ovarian cancer	Combination chemotherapy: Paclitaxel, carboplatin with or without bevacizumab, or Docetaxel, carboplatin, or Paclitaxel, cisplatin	Gemcitabine, liposomal doxorubicin, topotecan, cyclophosphamide, etoposide, pemetrexed, olaparib, pazopanib, rucaparib
Cervical cancer	With radiation: Cisplatin Combination chemotherapy: Cisplatin, paclitaxel with or without bevacizumab, or Cisplatin, topotecan, or Carboplatin, paclitaxel with or without bevacizumab, or Cisplatin, gemcitabine, or Topotecan, paclitaxel with or without bevacizumab	Docetaxel, ifosfamide, vinorelbine, irinotecan, mitomycin, fluorouracil, pemetrexed, bevacizumab, pembrolizumab
Breast cancer	Adjuvant hormone therapy: <i>Premenopausal:</i> Tamoxifen <i>Postmenopausal:</i> Aromatase inhibitors (anastrozole, letrozol, exemestane) Adjuvant chemotherapy (without trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, or Docetaxel, cyclophosphamide, or Doxorubicin, cyclophosphamide, docetaxel Adjuvant chemotherapy (with trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, trastuzumab with or without pertuzumab, or Docetaxel, carboplatin, trastuzumab with or without pertuzumab	Eribulin, capecitabine, mitoxantrone, cisplatin, etoposide, vinblastine, fluorouracil, ixabepilone, pertuzumab, gemcitabine, lapatinib, toremifene, fulvestrant, palbociclib, raloxifene, abemaciclib, ribociclib, olaparib
Choriocarcinoma (trophoblastic neoplasms)	Single-agent chemotherapy: Methotrexate or dactinomycin for low-risk disease Combination chemotherapy: Etoposide, methotrexate, dactinomycin, cyclophosphamide, vincristine (EMA-CO) for high-risk disease	Vinblastine, cisplatin, mercaptopurine, chlorambucil, doxorubicin
Testicular cancer	Combination chemotherapy: Cisplatin, etoposide (EP), or Bleomycin, etoposide, cisplatin (BEP), or Etoposide, mesna, ifosfamide, cisplatin (VIP)	Vinblastine, paclitaxel, gemcitabine, oxaliplatin
Kidney (renal cell) cancer	Single-agent chemotherapy: Sunitinib or temsirolimus or bevacizumab or sorafenib or pazopanib or axitinib or interleukin-2	Interferon-alpha, cabozantinib, nivolumab, lenvatinib

(continued)

Table 39–2. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Bladder cancer	Combination chemotherapy: Gemcitabine, cisplatin, or Methotrexate, vinblastine, doxorubicin, cisplatin (MVAC), or Cisplatin, methotrexate, vinblastine (CMV)	Atezolizumab, carboplatin, paclitaxel, docetaxel, fluorouracil, pemetrexed, pembrolizumab, durvalumab, avelumab
Prostate cancer	Hormone therapy: Luteinizing hormone–releasing agonist (leuprolide, goserelin, triptorelin, histrelin, degarelix) with or without an antiandrogen (flutamide, bicalutamide, nilutamide) Chemotherapy: Tocetaxel, prednisone	Ketoconazole, abiraterone, enzalutamide, mitoxantrone, cabazitaxel, sipuleucel-T, prednisone, Radium (Ra)-223
Brain cancer (anaplastic astrocytoma and glioblastoma multiforme)	Single-agent chemotherapy with radiation therapy: Temozolomide	Bevacizumab, irinotecan, procarbazine, carmustine, lomustine, cyclophosphamide, etoposide
Neuroblastoma	Combination chemotherapy: Cyclophosphamide, doxorubicin, cisplatin, etoposide	Vincristine, topotecan, irinotecan, ifosfamide, carboplatin, 13-cis-retinoic acid, ¹³¹ I-MIBG, dinutuximab, autologous or allogeneic transplantation
Thyroid cancer	Single-agent chemotherapy: Radioiodine (¹³¹ I) or sorafenib, or sunitinib or pazopanib or lenvatinib, vandetanib or cabozantinib (medullary thyroid cancer) Combination chemotherapy: Paclitaxel/carboplatin or docetaxel/doxorubicin (anaplastic carcinoma)	Doxorubicin, dacarbazine
Adrenal cancer	Single-agent chemotherapy: Mitotane	Doxorubicin, etoposide, cisplatin
Stomach (gastric) cancer	Combination chemotherapy: Epirubicin, cisplatin, fluorouracil, or Docetaxel, cisplatin, fluorouracil, or Cisplatin, fluorouracil, Fluorouracil, oxaliplatin Trastuzumab added for <i>HER2</i> -overexpressing adenocarcinomas	Capecitabine, irinotecan, paclitaxel, ramucirumab, pembrolizumab (MSI-H or dMMR tumors)
Pancreatic cancer	Combination chemotherapy: Gemcitabine, nab-paclitaxel, or 5-Fluorouracil, leucovorin, irinotecan, oxaliplatin (FOLFIRINOX) Single-agent chemotherapy: Gemcitabine	Gemcitabine, capecitabine 5-Fluorouracil, leucovorin, nanoliposomal irinotecan 5-Fluorouracil, folinic acid, oxaliplatin (FOLFOX) Pembrolizumab (MSI-H or dMMR or PD-L1 positive tumors) Capecitabine
Colon cancer	Combination chemotherapy: Fluorouracil, leucovorin, oxaliplatin (FOLFOX), or Capecitabine, oxaliplatin (CapeOx), or Fluorouracil, leucovorin, irinotecan (FOLFIRI) each regimen with or without bevacizumab	Cetuximab, panitumumab, regorafenib, ziv-aflibercept, trifluridine/tipiracil, nivolumab or pembrolizumab (dMMR/MSI-H only)
Rectal cancer	Chemotherapy with radiation: Fluorouracil or capecitabine; For adjuvant or advanced disease treatment, same regimens used with colon cancer	Cetuximab, panitumumab, regorafenib, ziv-aflibercept, trifluridine/tipiracil, nivolumab or pembrolizumab (dMMR/MSI-H only)
Anal cancer	Combination chemotherapy with radiation: Fluorouracil, mitomycin or capecitabine, mitomycin	Cisplatin
Carcinoid	Octreotide LAR or lanreotide	Doxorubicin, dacarbazine, temozolomide, capecitabine, streptozocin, oxaliplatin, fluorouracil, everolimus
Osteogenic sarcoma	Combination chemotherapy: Cisplatin, doxorubicin, or Methotrexate, cisplatin, doxorubicin, or Ifosfamide, cisplatin, epirubicin	Cyclophosphamide, gemcitabine, docetaxel, etoposide, sorafenib, everolimus, Radium (Ra)-223, Samarium (Sm)-153 (lexidronam)-ethylene diamine tetramethylene phosphate (EDTMP), pembrolizumab (MSI-H or dMMR tumors)

(continued)

Table 39–2. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Soft tissue sarcomas	Combination chemotherapy: Doxorubicin, dacarbazine (AD), or Doxorubicin, ifosfamide, mesna (AIM), or Mesna, doxorubicin, ifosfamide, dacarbazine (MAID), or Doxorubicin, olaratumab Single-agent chemotherapy: Eribulin, pazopanib; imatinib or sunitinib or regorafenib (gastrointestinal stromal tumors)	Liposomal doxorubicin, methotrexate, gemcitabine, docetaxel, temozolomide, epirubicin, pazopanib, eribulin, trabectedin; sorafenib, nilotinib, dasatinib, pazopanib, regorafenib, everolimus (gastrointestinal stromal tumors)
Melanoma	Combination chemotherapy (non-<i>BRAF</i> mutation): nivolumab/ipilimumab Combination chemotherapy (<i>BRAF</i> mutation): dabrafenib/trametinib or vemurafenib/cobimetinib Single-agent chemotherapy (non-<i>BRAF</i> mutation): pembrolizumab or nivolumab Single-agent chemotherapy (<i>BRAF</i> mutation): vemurafenib or dabrafenib	Dacarbazine, temozolomide, imatinib, paclitaxel, carboplatin, IL-2, interferon alfa-2b
Hepatocellular cancer	Single-agent chemotherapy: Sorafenib	Regorafenib, nivolumab
Kaposi sarcoma	Single-agent chemotherapy: Liposomal doxorubicin or liposomal daunorubicin	Paclitaxel, vinblastine, vincristine, etoposide, thalidomide, gemcitabine, sirolimus

dMMR, deficiency in mismatch repair proteins; MSI-H, microsatellite instability-high; PD-L1, programmed death-ligand 1.

Table 39–3. Common chemotherapeutic agents.¹

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Alkylating Agents—Nitrogen Mustards		
Bendamustine (Treanda)	100–120 mg/m ² intravenously every 3–4 weeks	Acute: hypersensitivity, nausea, vomiting Delayed: myelosuppression, rash, pyrexia, fatigue
Cyclophosphamide (Cytoxan)	500–1000 mg/m ² intravenously every 3 weeks; 100 mg/m ² /day orally for 14 days every 4 weeks; various doses	Acute: nausea and vomiting Delayed: myelosuppression, alopecia, hemorrhagic cystitis, cardiotoxicity (high dose)
Ifosfamide (Ifex)	1200 mg/m ² intravenously daily for 5 days every 3 weeks; various doses	Acute: nausea and vomiting Delayed: alopecia, myelosuppression, hemorrhagic cystitis, neurotoxicity
Melphalan (Alkeran)	0.25 mg/kg/day or 8–10 mg/m ² /day orally for 4 days every 4–6 weeks; 16 mg/m ² intravenously every 2–4 weeks; various doses	Acute: nausea, vomiting, diarrhea, hypersensitivity (intravenously) Delayed: mucositis (intravenously), myelosuppression, increased risk of secondary malignancies
Alkylating Agents—Platinum Analogs		
Carboplatin (Paraplatin)	Area under the curve (AUC)-based dosing use Calvert equation [Dose (mg) = AUC × (GFR + 25)] AUC = 2–7 mg/mL/min every 2–4 weeks	Acute: nausea and vomiting Delayed: myelosuppression, electrolyte disturbances, peripheral neuropathy, nephrotoxicity, hypersensitivity
Cisplatin (Platinol)	50–100 mg/m ² intravenously every 3–4 weeks; 20 mg/m ² /day intravenously for 5 days every 3 weeks; various doses	Acute: nausea and vomiting Delayed: nephrotoxicity, ototoxicity, neurotoxicity, myelosuppression, electrolyte disturbances
Oxaliplatin (Eloxatin)	85–130 mg/m ² intravenously every 2–3 weeks	Acute: peripheral neuropathy exacerbated by cold, nausea, vomiting, diarrhea Delayed: myelosuppression, elevated transaminases

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Alkylating Agents—Triazines		
Dacarbazine (DTIC-Dome)	375 mg/m ² intravenously on day 1 and 15 every 4 weeks; 900–1000 mg/m ² intravenously over 3 to 4 days; various doses	Acute: nausea, vomiting, photosensitivity Delayed: myelosuppression, anorexia, hypotension, flu-like syndrome
Procarbazine (Matulane)	60–100 mg/m ² orally for 14 days every 4 weeks; various doses	Acute: nausea and vomiting Delayed: myelosuppression, disulfiram-like reaction, MAO inhibition, rash
Temozolomide (Temodar)	75 mg/m ² orally daily during radiation for 42 days; 150–200 mg/m ² orally for 5 days every 4 weeks	Acute: nausea, vomiting, constipation Delayed: myelosuppression, fatigue
Alkylating Agent—Miscellaneous		
Busulfan (Myleran)	1–8 mg orally daily; 0.8 mg/kg intravenously every 6 hours for 4 days	Acute: nausea and vomiting Delayed: myelosuppression, mucositis, rash, edema, electrolyte disturbances, hepatic veno-occlusive disease (high dose)
Chlorambucil (Leukeran)	0.1–0.2 mg/kg/day orally for 3–6 weeks; 0.4 mg/kg pulse every 4 weeks	Acute: nausea Delayed: myelosuppression, rash
Antimetabolites—Folate Antagonists		
Methotrexate (MTX; Trexall)	Intrathecal: 12 mg High dose: 1000–12,000 mg/m ² intravenously every 2–3 weeks	Acute: nausea, vomiting, mucositis Delayed: myelosuppression, nephrotoxicity, hepatotoxicity, neurotoxicity, photosensitivity, pulmonary toxicity
Pemetrexed (Alimta)	500 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, rash Delayed: myelosuppression, fatigue, mucositis
Antimetabolites—Purine Analogs		
Cladribine (Leustatin)	0.1 mg/kg/day subcutaneously daily for 5 days or 0.09 mg/kg/day intravenously via continuous infusion for 7 days	Acute: nausea, injection site reaction Delayed: myelosuppression, immunosuppression, fever, fatigue, rash
Clofarabine (Clolar)	52 mg/m ² intravenously daily for 5 days every 2–6 weeks (for patients < 21 years of age)	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, hepatotoxicity, nephrotoxicity, rash, capillary leak syndrome
Fludarabine (Fludara)	25 mg/m ² intravenously for 5 days every 4 weeks	Acute: fever, nausea, vomiting Delayed: asthenia, myelosuppression, immunosuppression, neurotoxicity, anorexia
Mercaptopurine (6-MP; Purinethol)	Induction: 2.5–5 mg/kg/day orally Maintenance: 1.5–2.5 mg/kg/day orally	Acute: nausea, vomiting, diarrhea, rash Delayed: myelosuppression, immunosuppression, hepatotoxicity, mucositis
Pentostatin (Nipent)	2–4 mg/m ² intravenously every 2–3 weeks	Acute: nausea, vomiting, rash Delayed: myelosuppression, fever, myalgia, immunosuppression, hepatotoxicity, cough
Antimetabolites—Pyrimidine Analogs		
Azacitidine (Vidaza)	75–100 mg/m ² subcutaneously or intravenously for 7 days every 4 weeks	Acute: injection site reaction (subcutaneously), nausea, diarrhea, fever Delayed: myelosuppression, dyspnea, arthralgia
Capecitabine (Xeloda)	1000–1250 mg/m ² orally twice a day for 14 days every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: hand-foot syndrome, mucositis, hyperbilirubinemia, myelosuppression
Cytarabine (Ara-C, Cytosar U)	Standard dose: 100 mg/m ² /day intravenously via continuous infusion for 7 days High dose: 1000–3000 mg/m ² intravenously every 12 hours for 2–6 days	Acute: nausea, vomiting, rash, flu-like syndrome Delayed: myelosuppression High-dose: neurotoxicity, ocular toxicities
Decitabine (Dacogen)	15 mg/m ² intravenously every 8 hours for 3 days every 8 weeks; 20 mg/m ² intravenously daily for 5 days	Acute: nausea, vomiting, hyperglycemia Delayed: myelosuppression, fever, fatigue, cough

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Fluorouracil (Aduclil)	400 mg/m ² intravenous bolus followed by 2400 mg/m ² intravenously over 46 hours every 2 weeks; 1000 mg/m ² intravenously via continuous infusion for 4–5 days every 3–4 weeks; various doses	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, hand-foot syndrome, mucositis, photosensitivity, cardiotoxicity (rare)
Gemcitabine (Gemzar)	1000–1250 mg/m ² intravenously on days 1 and 8 every 3 weeks or days 1, 8, 15 every 4 weeks	Acute: nausea, vomiting, rash, flu-like symptoms, fever, diarrhea Delayed: myelosuppression, edema, elevated transaminases
Antimicrotubules—Vinca Alkaloids		
Vinblastine (Velban)	6 mg/m ² intravenously on days 1 and 15 every 4 weeks; various doses	Acute: constipation Delayed: myelosuppression, alopecia, bone pain, malaise
Vincristine (Oncovin)	0.5–1.4 mg/m ² intravenously every 3 weeks; various doses; maximum single dose usually limited to 2 mg	Acute: constipation, nausea Delayed: peripheral neuropathy, alopecia
Vinorelbine (Navelbine)	25–30 mg/m ² intravenously weekly	Acute: nausea, vomiting Delayed: myelosuppression, peripheral neuropathy, constipation, alopecia, asthenia
Antimicrotubules—Taxanes		
Cabazitaxel (Jevtana)	25 mg/m ² intravenously every 3 weeks	Acute: diarrhea, nausea, vomiting, hypersensitivity Delayed: myelosuppression, peripheral neuropathy, fatigue
Docetaxel (Taxotere)	60–100 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity, rash Delayed: myelosuppression, asthenia, peripheral neuropathy, alopecia, edema, mucositis
Paclitaxel (Taxol)	135–175 mg/m ² intravenously every 3 weeks; 50–80 mg/m ² intravenously weekly; various doses	Acute: diarrhea, nausea, vomiting, hypersensitivity Delayed: myelosuppression, peripheral neuropathy, alopecia, mucositis, arthralgia
Paclitaxel protein-bound (Abraxane)	100–125 mg/m ² on days 1, 8, 15 every 3–4 weeks; 260 mg/m ² intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, peripheral neuropathy, alopecia, asthenia
Enzyme Inhibitors—Anthracyclines		
Daunorubicin (Cerubidine)	30–60 mg/m ² intravenously for 3 days	Acute: nausea, vomiting, diarrhea, red/orange discoloration of urine, infusion-related reactions (liposomal products) Delayed: myelosuppression, mucositis, alopecia, hand-foot syndrome (liposomal doxorubicin), cardiotoxicity (dose related)
Doxorubicin (Adriamycin)	45–75 mg/m ² intravenously every 3 weeks; various doses	
Epirubicin (Ellence)	60–120 mg/m ² intravenously every 3–4 weeks	
Idarubicin (Idamycin)	10–12 mg/m ² intravenously for 3 days	
Liposomal Daunorubicin (DaunoXome)	40 mg/m ² intravenously every 2 weeks	
Liposomal Doxorubicin (Lipodox)	20–50 mg/m ² intravenously every 3–4 weeks	
Enzyme Inhibitors—Topoisomerase Inhibitors		
Etoposide (Vepesid)	50–100 mg/m ² intravenously for 3–5 days every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity, fever, hypotension Delayed: myelosuppression, alopecia, fatigue
Etoposide phosphate (Etopophos)	35–100 mg/m ² intravenously for 3–5 days every 3–4 weeks	

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Irinotecan (Camptosar)	180 mg/m ² intravenously every other week; various doses	Acute: diarrhea, cholinergic syndrome, nausea, vomiting Delayed: myelosuppression, alopecia, asthenia
Topotecan (Hycamtin)	1.5 mg/m ² intravenously for 5 days every 3 weeks; 2.3 mg/m ² orally for 5 days every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, alopecia, asthenia
Immunomodulatory Therapy		
Lenalidomide (Revlimid)	5–25 mg orally once daily on days 1–21 of 28-day cycle; or continuously	Acute: diarrhea, rash Delayed: myelosuppression, fatigue, venous thromboembolism, potential for birth defects
Pomalidomide (Pomalyst)	4 mg orally once daily on days 1–21 of 28-day cycle	Acute: nausea, diarrhea, dizziness Delayed: myelosuppression, fatigue, neuropathy, upper respiratory tract infections, venous thromboembolism, potential for birth defects
Thalidomide (Thalomid)	50–800 mg orally once daily	Acute: sedation, constipation, rash Delayed: edema, peripheral neuropathy, venous thromboembolism, potential for birth defects
Proteasome Inhibitors		
Bortezomib (Velcade)	1.3 mg/m ² intravenous bolus or subcutaneously on days 1, 4, 8, 11 followed by a 10-day rest, or weekly for 4 weeks followed by 13-day rest	Acute: nausea, vomiting, diarrhea Delayed: peripheral neuropathy, fatigue, myelosuppression
Carfilzomib (Kyprolis)	20 mg/m ² or 27 mg/m ² intravenously on days 1, 2, 8, 9, 15, 16 followed by a 12-day rest (28-day cycle)	Acute: nausea, dyspnea, diarrhea, infusion-related reaction Delayed: fatigue, myelosuppression, elevated serum creatinine
Ixazomib (Ninlaro)	4 mg orally on days 1, 8, 15 of a 28-day treatment cycle	Acute: diarrhea, constipation, nausea, vomiting Delayed: myelosuppression, peripheral neuropathy, peripheral edema, rash, hepatotoxicity (rare)
Targeted Therapy—Monoclonal Antibodies		
Ado-trastuzumab emtansine (Kadcyla)	3.6 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea Delayed: fatigue, musculoskeletal pain, thrombocytopenia, cardiotoxicity, hepatotoxicity
Alemtuzumab (Campath)	3–10 mg intravenously or subcutaneously three times weekly	Acute: infusion-related reaction, nausea, vomiting, hypotension, rash Delayed: myelosuppression, immunosuppression
Atezolizumab (Tecentriq)	1200 mg intravenously every 3 weeks	Acute: infusion-related reaction Delayed: immune-mediated reactions, fatigue, decreased appetite
Bevacizumab (Avastin)	5–15 mg/kg intravenously every 2–3 weeks	Acute: infusion-related reaction Delayed: hypertension, proteinuria, wound healing complications, gastrointestinal perforation, hemorrhage
Brentuximab vedotin (Adcetris)	1.8 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea, vomiting, diarrhea Delayed: myelosuppression, peripheral neuropathy, fatigue, rash, cough
Cetuximab (Erbix)	Loading dose 400 mg/m ² intravenously, maintenance dose 250 mg/m ² intravenously weekly	Acute: infusion-related reaction, nausea, diarrhea Delayed: acneiform skin rash, hypomagnesemia, asthenia, paronychia inflammation, dyspnea
Daratumumab (Darzalex)	16 mg/kg intravenously weekly for weeks 1–8, every 2 weeks for weeks 9–24, and every 4 weeks from week 25 until disease progression	Acute: infusion-related reaction, nausea Delayed: myelosuppression, fatigue, upper respiratory tract infection
Elotuzumab (Empliciti)	10 mg/kg intravenously every week for the first 2 cycles and every 2 weeks thereafter	Acute: infusion-related reaction, diarrhea Delayed: fatigue, peripheral neuropathy, risk for opportunistic infections

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Ipilimumab (Yervoy)	3 mg/kg intravenously every 3 weeks for a total of four doses	Acute: infusion-related reaction Delayed: immune-related reactions, fatigue
Necitumumab (Portrazza)	800 mg intravenously over 60 mins prior to gemcitabine and cisplatin on days 1 and 8 of 21-day cycle	Acute: infusion-related reaction, vomiting, diarrhea Delayed: electrolyte abnormalities (especially hypomagnesemia), rash, cardiopulmonary arrest (rare)
Nivolumab (Opdivo)	3 mg/kg intravenously over 1 hour every 2 weeks	Acute: vomiting Delayed: fatigue, musculoskeletal pain, rash, pruritus, cough, elevated transaminases
Obinutuzumab (Gazyva)	Cycle 1: 100 mg intravenously on day 1, 900 mg on day 2, 1000 mg on day 8 and 15 of a 28-day cycle; Cycles 2–6: 1000 mg intravenously on day 1	Acute: infusion-related reaction, tumor lysis syndrome Delayed: myelosuppression, pyrexia, cough, musculoskeletal disorder, potential hepatitis B reactivation
Ofatumumab (Arzerra)	300 mg initial dose intravenously, followed 1 week later by 2000 mg intravenously weekly for 7 doses, followed 4 weeks later by 2000 mg intravenously every 4 weeks for four doses; or 300 mg initial dose intravenously, followed 1 week later by 1000 mg intravenously, then 1000 mg intravenously every 4 weeks	Acute: infusion-related reaction, diarrhea, nausea Delayed: neutropenia, infections, pyrexia, rash, fatigue, potential hepatitis B reactivation
Olaratumab (Lartruvo)	15 mg/kg intravenously on days 1 and 8 of a 21-day cycle	Acute: nausea, vomiting, infusion-related reaction Delayed: fatigue, musculoskeletal pain, mucositis, alopecia
Panitumumab (Vectibix)	6 mg/kg intravenously every 2 weeks	Acute: infusion-related reaction, nausea Delayed: acneiform skin rash, hypomagnesemia, asthenia, paronychia, fatigue, dyspnea
Pembrolizumab (Keytruda)	2 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, nausea Delayed: immune-mediated reactions, fatigue, cough
Pertuzumab (Perjeta)	840 mg intravenously once followed by 420 mg intravenously every 3 weeks	Acute: infusion-related reaction, diarrhea, nausea Delayed: fatigue, alopecia, neutropenia, rash, peripheral neuropathy, cardiomyopathy
Ramucirumab (Cyramza)	8 mg/kg intravenously every 2 weeks or 10 mg/kg intravenously every 3 weeks	Acute: infusion-related reaction, hypertension, diarrhea Delayed: fatigue, neutropenia, epistaxis
Rituximab (Rituxan)	375 mg/m ² intravenously weekly for 4 weeks, or every 3–4 weeks	Acute: infusion-related reaction, tumor lysis syndrome Delayed: lymphopenia, asthenia, rash, potential hepatitis B reactivation
Trastuzumab (Herceptin)	Initial dose 4 mg/kg intravenously, then 2 mg/kg intravenously weekly; or initial dose 8 mg/kg then 6 mg/kg, intravenously every 3 weeks	Acute: headache, nausea, diarrhea, infusion-related reaction Delayed: myelosuppression, pyrexia, cardiomyopathy, pulmonary toxicity (rare)
Targeted Therapy—Kinase Inhibitors		
Afatinib (Gilotrif)	40 mg orally once daily without food	Acute: diarrhea Delayed: acneiform rash, stomatitis, paronychia
Alectinib (Alecensa)	600 mg orally twice daily with food	Acute: none Delayed: myelosuppression, fatigue, edema, myalgia, dyspnea, elevated transaminases
Axitinib (Inlyta)	5–10 mg orally twice daily	Acute: diarrhea, nausea, vomiting Delayed: hypertension, fatigue, dysphonia, hand-foot syndrome, elevated transaminases
Bosutinib (Bosulif)	500–600 mg orally once daily with food	Acute: diarrhea, nausea, vomiting Delayed: myelosuppression, rash, abdominal pain, hepatotoxicity, fluid retention
Ceritinib (Zykadia)	740 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: elevated transaminases, abdominal pain, fatigue, decreased appetite

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Cobimetinib (Cotellic)	60 mg orally once daily on days 1 to 21 of a 28-day cycle	Acute: diarrhea, photosensitivity reaction, nausea, vomiting Delayed: myelosuppression, hepatotoxicity, rash, cardiomyopathy (with vemurafenib)
Crizotinib (Xalkori)	250 mg orally twice daily	Acute: nausea, vomiting, diarrhea, constipation Delayed: vision disorder, edema, elevated transaminases, fatigue
Dabrafenib (Tafinlar)	150 mg orally twice daily without food	Acute: headache Delayed: hyperkeratosis, fever, hand-foot syndrome, hyperglycemia, hypophosphatemia
Dasatinib (Sprycel)	100–180 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: myelosuppression, fluid retention, fatigue, dyspnea, musculoskeletal pain, rash
Erlotinib (Tarceva)	100 or 150 mg orally once daily without food	Acute: diarrhea, nausea, vomiting Delayed: acneiform skin rash, fatigue, anorexia, dyspnea
Everolimus (Afinitor)	10 mg orally once daily	Acute: mucositis, diarrhea, nausea Delayed: myelosuppression, fatigue, edema, hypercholesterolemia, hypertriglyceridemia, hyperglycemia
Gefitinib (Iressa)	250 mg orally once daily	Acute: diarrhea Delayed: acneiform skin rash
Ibrutinib (Imbruvica)	420 mg or 560 mg orally once daily	Acute: diarrhea, nausea Delayed: myelosuppression, fatigue, edema, rash, elevated serum creatinine, hemorrhage
Idelalisib (Zydelig)	150 mg orally twice daily	Acute: diarrhea, nausea Delayed: hepatotoxicity, pneumonitis, intestinal perforation, pyrexia, fatigue, neutropenia, hypertriglyceridemia, hyperglycemia
Imatinib (Gleevec)	100–800 mg orally once daily with food	Acute: nausea, vomiting, diarrhea Delayed: edema, muscle cramps, rash, myelosuppression, hepatotoxicity
Lapatinib (Tykerb)	1250 mg or 1500 mg orally once daily	Acute: diarrhea, nausea, vomiting Delayed: hand-foot syndrome, fatigue, hepatotoxicity (rare)
Lenvatinib (Lenvima)	24 mg orally daily	Acute: hypertension, nausea, vomiting, diarrhea Delayed: fatigue, arthralgia/myalgia, stomatitis, hand-foot syndrome
Nilotinib (Tasigna)	300 or 400 mg orally twice daily without food	Acute: nausea, vomiting, diarrhea Delayed: rash, fatigue, myelosuppression, prolonged QT interval (rare)
Osimertinib (Tagrisso)	80 mg orally once daily	Acute: diarrhea Delayed: myelosuppression, rash, dry skin, nail toxicity, cardiomyopathy (rare), QTc interval prolongation (rare)
Palbociclib (Ibrance)	125 mg orally daily with food for 21 days followed by 7 days off	Acute: nausea, diarrhea, vomiting Delayed: myelosuppression, fatigue, upper respiratory infection, stomatitis, alopecia
Pazopanib (Votrient)	800 mg orally once daily without food	Acute: diarrhea, nausea, vomiting Delayed: hypertension, hair color changes, hepatotoxicity, hemorrhage
Regorafenib (Stivarga)	160 mg orally once daily with food (low-fat breakfast)	Acute: diarrhea Delayed: asthenia, hand-foot syndrome, anorexia, hypertension, mucositis, myelosuppression, hepatotoxicity

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Sorafenib (Nexavar)	400 mg orally twice daily without food	Acute: diarrhea and nausea Delayed: fatigue, hand-foot syndrome, rash, hypertension, hemorrhage
Sunitinib (Sutent)	50 mg orally once daily for 4 weeks followed by 2 weeks rest; 37.5 mg orally daily	Acute: diarrhea and nausea Delayed: hypertension, hand-foot syndrome, rash, yellow discoloration of skin, fatigue, hypothyroidism, mucositis, left ventricular dysfunction, bleeding, hepatotoxicity
Temsirolimus (Torisel)	25 mg intravenously weekly	Acute: hypersensitivity, rash Delayed: myelosuppression, asthenia, hyperglycemia, hyperlipidemia, elevated serum creatinine
Trametinib (Mekinist)	2 mg orally once daily without food	Acute: rash, diarrhea Delayed: elevated transaminases, lymphedema, cardiomyopathy
Vemurafenib (Zelboraf)	960 mg orally twice daily	Acute: nausea, hypersensitivity (rare) Delayed: photosensitivity, rash, arthralgia, alopecia, fatigue, prolonged QT interval, cutaneous squamous cell carcinoma
Miscellaneous Agents		
Arsenic trioxide (Trisenox)	0.15 mg/kg intravenously daily	Acute: nausea, dizziness Delayed: acute promyelocytic leukemia differentiation syndrome, prolonged QT interval
Asparaginase Erwinia chrysanthemi (Erwinaze)	25,000 international units/m ² intramuscularly three times weekly	Acute: hypersensitivity, nausea, vomiting Delayed: coagulation abnormalities, hepatotoxicity, pancreatitis, neurotoxicity
Bleomycin (Blenoxane)	10 units/m ² intravenously on days 1 and 15 every 28 days; 30 units intravenously on day 2, 9, and 16 every 21 days	Acute: hypersensitivity, fever Delayed: skin reaction (rash, hyperpigmentation of skin, striae), mucositis, pneumonitis
Dactinomycin (Cosmegen)	15 mcg/kg or 400–600 mcg/m ² intravenously daily for 5 days	Acute: nausea, vomiting Delayed: myelosuppression, mucositis, rash, diarrhea, hepatoveno-occlusive disease (rare)
Hydroxyurea (Hydrea)	20–30 mg/kg orally daily	Acute: none Delayed: myelosuppression
Mitomycin (Mutamycin)	10–20 mg/m ² intravenously every 4–8 weeks; 20–40 mg intravesically	Acute: cystitis (intravesically), nausea, vomiting Delayed: myelosuppression, mucositis, anorexia
Mitoxantrone (Novantrone)	12–14 mg/m ² intravenously every 3 weeks; 12 mg/m ² intravenously for 2–3 days	Acute: nausea, vomiting, diarrhea, mucositis, blue-green discoloration of urine Delayed: myelosuppression, alopecia, cardiotoxicity
Omacetaxine mepe-succinate (Synribo)	Induction: 1.25 mg/m ² subcutaneously twice daily for 14 days every 28 days Maintenance: 1.25 mg/m ² subcutaneously twice daily for 7 days every 28 days	Acute: diarrhea, nausea, fatigue, injection site reaction Delayed: myelosuppression, infection
Panobinostat (Farydak)	20 mg orally per day on days 1, 3, 5, 8, 10, 12 of each 21-day cycle	Acute: diarrhea, nausea Delayed: myelosuppression, electrolyte abnormalities, infections
Tretinoin (All-Trans-Retinoic Acid, ATRA, Vesanoid)	45 mg/m ² orally divided twice daily for 45–90 days or 30 days past complete remission	Acute: headache, nausea Delayed: vitamin A toxicity, retinoic acid-acute promyelocytic leukemia syndrome
Trifluridine/tipiracil (Lonsurf)	35 mg/m ² based on trifluridine component orally twice daily within 1 hour of meal on days 1–5 and 8–12 (28-day cycle)	Acute: nausea, diarrhea, vomiting Delayed: myelosuppression, fatigue, anorexia

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Venetoclax (Venclexta)	20 mg orally daily during week 1; 50 mg daily during week 2; 100 mg daily during week 3; 200 mg daily during week 4; then 400 mg orally daily thereafter	Acute: diarrhea, nausea, vomiting, tumor lysis syndrome Delayed: myelosuppression, upper respiratory infections, fatigue
Ziv-aflibercept (Zaltrap)	4 mg/kg intravenously every 2 weeks	Acute: diarrhea Delayed: myelosuppression, proteinuria, elevated transaminases, stomatitis, fatigue, hypertension
Antiandrogens		
Bicalutamide (Casodex)	50 mg orally once daily	Acute: none Delayed: hot flashes, back pain, asthenia
Enzalutamide (Xtandi)	160 mg orally once daily	Acute: asthenia, diarrhea Delayed: hot flashes, arthralgia, peripheral edema
Flutamide (Eulexin)	250 mg orally every 8 hours	Acute: diarrhea Delayed: hot flashes, hepatotoxicity
Nilutamide (Nilandron)	300 mg orally for 30 days, then 150 mg orally once daily	Acute: none Delayed: visual disturbances (impaired adaptation to dark), hot flashes, disulfiram-like reaction
Selective Estrogen Receptor Modulators		
Tamoxifen (Nolvadex)	20–40 mg orally once daily	Acute: none Delayed: hot flashes, vaginal discharge, menstrual irregularities, arthralgia
Toremifene (Fareston)	60 mg orally once daily	Acute: nausea Delayed: hot flashes, vaginal discharge
Aromatase Inhibitors		
Anastrozole (Arimidex)	1 mg orally once daily	Acute: nausea Delayed: hot flashes, peripheral edema, asthenia, hypercholesterolemia, arthralgia/myalgia, osteoporosis
Exemestane (Aromasin)	25 mg orally once daily	
Letrozole (Femara)	2.5 mg orally once daily	
Pure Estrogen Receptor Antagonist		
Fulvestrant (Faslodex)	500 mg intramuscularly on days 1, 15, 29, then monthly	Acute: injection site reaction, nausea Delayed: hot flashes, bone pain, elevated transaminases
LHRH Analogs		
Goserelin acetate (Zoladex)	3.6 mg subcutaneously every month; 10.8 mg subcutaneously every 3 months	Acute: injection site discomfort Delayed: hot flashes, tumor flare, edema, decreased libido, erectile dysfunction, osteoporosis
Leuprolide (Lupron)	7.5 mg intramuscularly or subcutaneously every month; 22.5 mg intramuscularly or subcutaneously every 3 months; 30 mg intramuscularly or subcutaneously every 4 months; 45 mg intramuscularly or subcutaneously every 6 months	
Triptorelin pamoate (Trelstar)	3.75 mg intramuscularly every 4 weeks; 11.25 mg intramuscularly every 12 weeks; 22.5 mg every 24 weeks	
LHRH Antagonist		
Degarelix (Firmagon)	240 mg subcutaneously once, then 80 mg subcutaneously every 28 days	Acute: injection site reaction Delayed: hot flashes, weight gain, elevated transaminases, QT prolongation

(continued)

Table 39–3. Common chemotherapeutic agents.¹ (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Adverse Effects
Adrenocorticosteroid		
Abiraterone (Zytiga)	1000 mg orally once daily	Acute: diarrhea, edema Delayed: adrenal insufficiency, hepatotoxicity, joint pain, hypokalemia
Biologic Response Modifiers		
Aldesleukin (IL-2, Proleukin)	600,000 international units/kg intravenously every 8 hours for 14 doses, repeat after 9 days rest	Acute: hypotension, nausea, vomiting, diarrhea, flu-like syndrome, capillary leak syndrome Delayed: myelosuppression, confusion, somnolence, oliguria
Interferon-alpha-2b (Intron A)	20 million international units/m ² intravenously 5 days a week for 4 weeks, then 10 million international units/m ² subcutaneously three times a week for 48 weeks	Acute: flu-like syndrome, nausea, vomiting, diarrhea Delayed: myelosuppression, anorexia, alopecia, depression, elevated transaminases
Sipuleucel-T (Provenge)	One dose (minimum of 50 million autologous CD54 cells) intravenously every 2 weeks for three doses	Acute: infusion-related reaction, nausea, vomiting Delayed: fatigue, back pain, arthralgia

TYPES OF CANCER

LUNG CANCER

Sunny Wang, MD

BRONCHOGENIC CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ New cough or change in chronic cough.
- ▶ Dyspnea, hemoptysis, anorexia, weight loss.
- ▶ Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- ▶ Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates 222,500 new diagnoses and 155,870 deaths from lung cancer in the United States in 2017, accounting for approximately 13% of new cancer diagnoses and 26% of all cancer deaths.

Cigarette smoking causes 85–90% of cases of lung cancer. The causal connection between cigarettes and lung cancer is established not only epidemiologically but also through identification of carcinogens in tobacco smoke

and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer.

Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon, asbestos, diesel exhaust, ionizing radiation, metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens. A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis.

The median age at diagnosis of lung cancer in the United States is 70; it is unusual under the age of 40. The combined relative 5-year survival rate for all stages of lung cancer is currently 18%.

There are five main histologic categories of bronchogenic carcinoma. **Squamous cell carcinomas** (23% of cases, based on US SEER data 2010–2014) arise from the bronchial epithelium and often present as an intraluminal mass. They are usually centrally located and can present with hemoptysis. Squamous cell carcinomas stain for P63 and P40 on immunohistochemistry. **Adenocarcinomas** (47% of cases) arise from mucous glands or from any epithelial cell within or distal to the terminal bronchioles. They usually present as peripheral nodules or masses and stain for TTF-1 and Napsin-A on immunohistochemistry. **Adenocarcinomas in situ** (formerly **bronchioloalveolar cell carcinomas**) spread along preexisting alveolar structures (lepidic growth) without evidence of invasion. **Large cell carcinomas** (2% of cases) are a heterogeneous group of undifferentiated cancers that share large cells and do not fit into other categories. Large cell carcinomas are typically aggressive and have rapid doubling times. They present as central or peripheral masses. Cancers that are not better differentiated on pathologic review other than non-small

cell carcinomas (NSCLC) or carcinomas not otherwise specified make up about 15% of cases. **Small cell carcinomas** (13% of cases) are tumors of bronchial origin that typically begin centrally, infiltrating submucosally to cause narrowing of the bronchus without a discrete luminal mass. They are aggressive cancers that often involve regional or distant metastasis on presentation.

For purposes of staging and treatment, bronchogenic carcinomas are divided into small cell lung cancer (SCLC) and the other four types, labeled NSCLC.

► Clinical Findings

Lung cancer is symptomatic at diagnosis in a majority of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, either nonspecific chest pain or pain from bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–41). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Lambert-Eaton myasthenic syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. **Sputum cytology** is highly specific but insensitive; the yield is highest when there are

lesions in the central airways. **Thoracentesis** (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. The use of fluorescence bronchoscopy improves the ability to identify early endobronchial lesions, and endobronchial and transesophageal endoscopic ultrasound enhance the direction and yield of FNA of mediastinal nodes. Electromagnetic navigational bronchoscopy allows bronchoscopic approaches to small peripheral nodules. While the diagnostic yield of CT-guided biopsies of peripheral nodules approaches 80–90%, the rates of pneumothorax are significant (15–30%), especially in those with emphysema.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan (Figure 39–1). These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging **NSCLC**. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best chance for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into summary stages I–IV, and these are used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIB and stage IV disease do not benefit from surgery (Table 39–4). Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in selected cases as part of multimodality therapy.

SCLC is traditionally divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). It is also recommended to stage SCLC according to the TNM staging system.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic

▲ Figure 39-1. Squamous cell carcinoma of the left lung on chest radiograph (A) and CT scan (B). (Used, with permission, from David A. Kasper, DO, MBA in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count (CBC), serum electrolytes, calcium, creatinine, liver tests, lactate dehydrogenase, and albumin.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is key for staging candidates for resection. The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging alone does not provide definitive staging information. CT imaging helps determine where to biopsy, and how the mediastinum should be sampled.

Positron emission tomography (PET) using 2-¹⁸F fluoro-2-deoxyglucose (FDG) is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When mediastinal lymph nodes smaller than 1 cm are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows lymph nodes

Table 39-4. Five-year survival rates for non-small cell lung cancer, based on TNM staging.

Stage	TNM Subset	5-Year Survival for Clinical TNM	5-Year Survival for Pathologic TNM
0	Carcinoma in situ		
1A1	T1aN0M0	92%	90%
1A2	T1bN0M0	83%	85%
1A3	T1cN0M0	77%	80%
1B	T2aN0M0	68%	73%
1IA	T2bN0M0	60%	65%
1IB	T1/T2, N1M0 T3N0M0	53%	56%
1IIIA	T1/T2, N2M0 T3N1M0 T4, N0/N1, M0	36%	41%
1IIIB	T1/T2, N3M0 T3/T4, N2M0	26%	24%
1IIIC	T3/T4, N3M0	13%	12%
1IVA	Any T, Any N, M1a/M1b	10%	-
1IVB	Any T, Any N, M1c	0%	-

Copyright © Elsevier; and data from Goldstraw P et al. The IASLC Lung Cancer Staging Project: proposals for revision of the TNM stage groupings in the forthcoming (eighth) edition of the TNM classification for lung cancer. *J Thorac Oncol*. 2015 Sept;11(1):39-51

larger than 1 cm, the sensitivity and specificity are 95% and 76%, respectively.

The combination of PET and CT imaging has improved preoperative staging compared with CT or PET alone. Whole body fusion PET-CT imaging is most useful to confirm lack of regional or metastatic disease in NSCLC patients who are candidates for surgical resection.

Disadvantages of PET imaging include limited resolution below 1 cm and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections. PET-CT scans are also inadequate for evaluating brain metastases due to normal physiologic FDG uptake in the brain. Obtaining an MRI of the brain is important to rule out brain metastases in patients with SCLC and in patients with NSCLC with at least stage II disease or poorly differentiated histologies.

2. Preoperative assessment—See Chapter 3.

3. Pulmonary function testing—Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung

function (preoperative FEV₁ 2 L or more) are at low risk for complications from lobectomy or pneumonectomy. High-risk patients include those with a predicted postoperative FEV₁ less than 700 mL (or less than 40% of predicted FEV₁).

4. Screening—Screening with low-dose helical CT scans has been shown to improve mortality rates for lung cancer. The National Lung Screening Trial, a multicenter randomized US trial involving over 53,000 current and former heavy smokers, showed that screening annually with low-dose helical CT for 3 years yielded a 20% relative reduction in lung cancer mortality and 6.7% reduction in all-cause mortality compared to chest radiography. Given these findings, US professional organizations, including the US Preventive Services Task Force (USPSTF), have recommended screening with low-dose helical CT for lung cancer. Smoking cessation policies and efforts should be integrated with any screening program.

► Treatment

A. Non–Small Cell Lung Carcinoma

Surgical resection offers the best chance for cure of NSCLC. Therefore, the initial approach to the patient is determined by answering two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II and select cases of stage IB are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes if treated with resection alone. They should undergo multimodality treatment that includes chemotherapy or radiotherapy, or both. Inoperable stage IIIA and stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Stage IV patients are treated with systemic therapy (targeted therapy, chemotherapy, or immunotherapy) or symptom-based palliative therapy, or both.

Surgical approach affects outcome. In 1994, the North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group ($P = 0.008$) and a trend toward an increase in overall death rate (increase of 30%, $P = 0.08$) and increase in cancer-related death rate (increase of 50%, $P = 0.09$), compared with patients receiving lobectomy. However, for patients who cannot tolerate lobectomy, a sublobar resection (wedge resection or segmentectomy) may be considered.

Patients with clinical stage I primary NSCLC, who are not candidates for surgery because of significant comorbidity or other surgical contraindication, are candidates for stereotactic body radiotherapy. Stereotactic body radiotherapy, which is composed of multiple non-parallel

radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. For clinical stage I NSCLC, 3-year local control rates with stereotactic body radiotherapy exceed 90%, and large meta-analyses of nonrandomized data have shown 2-year survival at 70% and 5-year survival at 40%. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or select stage IIIB disease. Some studies suggest a survival advantage.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and a subset of stage IB disease where primary tumor size exceeds 4 cm. The Lung Adjuvant Cisplatin Evaluation Collaborative Group, a meta-analysis of the five largest cisplatin-based adjuvant trials, reported a 5% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery ($P = 0.005$) in patients with at least stage II disease.

For stage IIIB and stage IV NSCLC, options for therapy include targeted therapy (Table 39–3), cytotoxic chemotherapy, and immunotherapy (checkpoint inhibitors) (Table 39–2). The approach to therapy is individualized based on up-front molecular profiling and PD-L1 testing. Molecular profiling is offered as next-generation sequencing multi-gene assays. The key driver mutations in lung cancer currently include *EGFR*, *ALK*, *BRAF*, and *ROS1*, but only a minority of all lung cancer cases harbor these mutations. *K-ras* mutation is more commonly found among smokers but has not been targeted effectively. Difficulties in testing may arise when only small fine-needle aspirate biopsies are obtained; it is recommended that clinicians obtain core biopsies for sufficient tissue for analysis. PD-L1 expression is a flawed but currently actively used biomarker to assess possible response to checkpoint inhibitor therapy (specifically, programmed death-1 (PD-1) inhibitors).

Targeted therapy has played a pivotal role in advanced NSCLC (Tables 39–2 and 39–3). Activating *EGFR* mutations are found in approximately 10–20% of the white population and 30–48% in the Asian population and are usually found among nonsmokers to light smokers, females, and persons with nonsquamous histologies (particularly adenocarcinomas). For patients with *EGFR* mutations, an *EGFR* tyrosine kinase inhibitor (erlotinib, gefitinib, or afatinib) rather than platinum-based chemotherapy is the first-line treatment. Response rates with *EGFR* inhibitors in patients with *EGFR* mutation are at least 70%, and median overall survival is estimated at 21–33 months. Resistance to erlotinib or gefitinib generally occurs in 1 year, and a common mechanism of resistance is the development of a *T790M* mutation. Osimertinib, a third-generation irreversible *EGFR* tyrosine kinase inhibitor, has been FDA approved

for the treatment of patients with the *T790M* mutation, with response rates up to 60%.

Approximately 5% of all patients with NSCLC carry translocations of *ALK* resulting in novel fusion gene products with oncogenic activity. This is usually found in a comparatively younger population, with adenocarcinoma histology, and nonsmoking to light-smoking history. In a phase III trial of *ALK*-rearranged lung cancer patients, treatment with crizotinib (an *ALK*, *cMET* and *ROS1* tyrosine kinase inhibitor) showed a response rate over 70% compared with a rate of 45% among those treated with standard first-line chemotherapy, and an improvement in median progression-free survival of 10.9 vs 7 months, respectively. At 1 year, however, resistance develops in most patients taking crizotinib. Ceritinib, alectinib, and brigatinib, second-generation *ALK* inhibitors, have been shown to induce response rates of 50% in those patients with *ALK*-rearranged lung cancers resistant to crizotinib. One recent randomized trial has shown that alectinib compared to crizotinib in first-line treatment of *ALK*-rearranged lung cancers has superior response rates (83% vs 75%) and progression-free survival. Approximately 1–2% of NSCLC harbor *ROS1* rearrangements and are usually found among nonsmokers or light smokers with lung adenocarcinomas. *ROS1* rearranged lung cancers also respond to crizotinib with response rates over 70%. *BRAF* mutations have been found in 2% of NSCLC patients. The combination of dabrafenib (*BRAF* inhibitor) and trametinib (*MEK* inhibitor) has shown response rates of over 60% in patients with *BRAF V600E* mutations. Finally, *K-ras* mutations are found among 25% of patients with adenocarcinomas, are associated with smoking, and indicate a poor prognosis. Unfortunately, there is still no effective targeted approach to therapy for *K-ras* mutated lung cancers.

If no targetable mutations are found and there is inadequate PD-L1 expression on tumor cells, patients are offered cytotoxic chemotherapy (Table 39–2). Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival in patients with stage IIIB and stage IV NSCLC compared with supportive care alone, with the median survival increased from 5 months to a range of 8–12 months and 1-year survival rate to 30–40%. Palliative chemotherapy also leads to improved quality of life and symptom control, with first-line therapy involving a platinum-based regimen. Platinum-based doublet regimens consist of cisplatin or carboplatin combined with another agent, such as pemetrexed, gemcitabine, taxane, or vinorelbine. The choice of chemotherapeutic agent should be tailored to histologic subtype in NSCLC.

Immune checkpoint inhibition with PD-1 or PD-L1 inhibitors (nivolumab, pembrolizumab, atezolizumab, and durvalumab) are playing increasingly important roles in the treatment of NSCLC (Tables 39–2 and 39–3). Checkpoint inhibitors release T cells from the inhibitory signals they receive from tumor cells via the PD-1 pathway, restoring antitumor immunity. For patients with tumors staining greater than 50% for PDL-1, pembrolizumab outperforms first-line platinum-based chemotherapy, with response rates of 45% vs 28% and median progression-free survival of 10 months vs. 6 months. Regardless of PDL-1 staining intensity,

Table 39–5. Median survival for small cell lung carcinoma following treatment.

Stage	Mean 2-Year Survival	Median Survival
Limited	20–40%	15–20 months
Extensive	5%	8–13 months

Data from multiple sources, including Van Meerbeeck JP et al. Small-cell lung cancer. *Lancet*. 2011 Nov 12;378(9804):1741–55.

PD-1 inhibitors are recommended as second-line treatment of both nonsquamous and squamous cell lung cancers, with approximately 20% response rates, with durable responses, and with superior overall and progression-free survival compared to standard second-line chemotherapy. Significant side effects and toxicity have been reported with autoimmune manifestations, such as hepatitis, thyroiditis, hypophysitis, colitis, pneumonitis, and type 1 diabetes mellitus.

B. Small Cell Lung Carcinoma

Response rates of SCLC to cisplatin and etoposide (Table 39–2) are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive-stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and 5% in extensive-stage disease (Table 39–5). Thoracic radiation therapy improves survival in patients with limited SCLC and is given concurrently with chemotherapy. Consolidative thoracic radiation therapy may be indicated for patients with extensive disease who have a significant response to chemotherapy and remain free of brain metastases. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited-stage disease who respond to chemotherapy and a subset of patients with extensive-stage disease who have had an excellent response to chemotherapy.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea, hemoptysis, endobronchial obstruction, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a *solitary* brain metastasis improves quality of life and survival when combined with radiation therapy if there is no evidence of other metastatic disease. Stereotactic radiation therapy is offered for limited brain metastases. Repeated thoracenteses, pleurodesis, or pleurex catheter tube placement are key interventions for

palliation of symptomatic malignant pleural effusions. Pain is very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5). In addition to standard oncologic care, early referral to a palliative care specialist is recommended in advanced disease to aid in symptom management and such palliative care can modestly improve survival.

Prognosis

The 5-year survival rate for lung cancer is approximately 18%. Predictors of survival include the type of tumor (SCLC versus NSCLC), molecular profiling, the stage of the tumor, the patient's performance status, and weight loss in the past 6 months. Patients with targetable mutations have better overall survival when compared with those without mutations due to superior efficacy of targeted drug therapy.

PULMONARY METASTASIS

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, infections (including abscesses, septic emboli, and atypical infections), sarcoidosis, rheumatoid nodules, and granulomatosis with polyangiitis. Metastases to the lungs are found in 20–55% of patients with various metastatic malignancies. Most are intraparenchymal. Carcinoma of the kidney, breast, rectum, colon, and cervix and malignant melanoma are the most likely primary tumors. Head and neck cancers with extensive or lower cervical nodal involvement have a 30% risk for distant metastasis; half of these metastases present in the lungs. Pulmonary metastases are common in patients with osteosarcomas and develop in approximately 20% of patients with soft tissue sarcomas.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor**

embolization from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available. If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, video-assisted thoracoscopic surgery (VATS), or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveals the diagnosis.

To determine a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, prostate-specific antigen (PSA) and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) and napsin-A are relatively specific for primary lung adenocarcinoma, while the former can be positive in cases of SCLC and thyroid carcinoma and the latter can be positive in papillary and clear cell renal cell carcinomas. An adenocarcinoma that demonstrates negative TTF-1 and napsin-A staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Mammography should be considered in women to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET-CT scan is helpful in identifying the site of a primary cancer and identifying other areas of extrathoracic metastasis.

Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (such as testis, colorectal, and kidney). Only about 15–25% of metastatic solid tumor patients have metastases limited to the lungs and are surgical candidates. Surgical resection should be considered only if the primary tumor is under control, if the patient has adequate cardiopulmonary reserve to tolerate resection, if all metastatic tumor can be resected, if effective nonsurgical approaches are not available, and if there is no evidence of extrathoracic metastases that are not controlled or controllable. Unfavorable prognostic factors also include shorter disease-free interval from primary tumor treatment to presentation of metastases and a larger number of metastases. Retrospective data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. Patients who are not surgical candidates but have solitary or limited metastatic disease to the lungs may be candidates for stereotactic radiotherapy, radioablation, or cryotherapy. For patients with unresectable progressive disease, chemotherapy tailored to the primary tumor can be offered, and diligent attention to palliative care is essential (see Chapter 5).

MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Unilateral, nonpleuritic chest pain and dyspnea.
- ▶ Distant (more than 20 years earlier) history of exposure to asbestos.
- ▶ Pleural effusion or pleural thickening or both on chest radiographs.
- ▶ Malignant cells in pleural fluid or tissue biopsy.

General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). Numerous studies have confirmed the association of **malignant pleural mesothelioma** with exposure to asbestos.

The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and other asbestos products (pipes, textiles, paints, tiles, gaskets, panels).

Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 72–74 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia.

Treatment

Chemotherapy is the mainstay of treatment (Tables 39–2 and 39–3), with surgery included in multimodality treatment only if there is localized disease that can be completely surgically resected with no evidence of mediastinal nodal involvement. The optimal surgical approach is still under debate. For localized disease, surgical options include pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to

diaphragm) or extrapleural pneumonectomy (a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm). Limited nonrandomized data have shown that a trimodality approach for localized disease with extrapleural pneumonectomy, adjuvant radiation, and (neoadjuvant or adjuvant) chemotherapy can prolong survival in highly selected patients. In advanced disease, palliative chemotherapy with cisplatin and pemetrexed can achieve response rates of 30–40%, can extend median overall survival to 12 months, and can improve quality of life. Adding bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) to cisplatin and pemetrexed has been shown to further improve overall survival. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit to some patients.

Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from diagnosis ranges from 7 months to 17 months. Five-year survival is 5–10%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survivals less than 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male gender, nodal involvement, elevated lactate dehydrogenase, high white blood cell count, low hemoglobin, and high platelet count.

HEPATOBIILIARY CANCERS

Lawrence S. Friedman, MD

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Usually a complication of cirrhosis.
- ▶ Characteristic CT and MRI features may obviate the need for a confirmatory biopsy.

General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas (accounting for 85% of liver cancers); those that originate in the ductular cells are called cholangiocarcinomas (15% or less). Rare tumors of the liver include angiosarcoma and lymphoma.

Hepatocellular carcinomas are associated with cirrhosis in 85% of cases. In Africa and most of Asia, hepatitis B virus (HBV) infection is a major etiologic factor, and a family history of hepatocellular carcinoma increases the risk synergistically. In the United States and other Western countries, incidence rates have risen rapidly (over twofold since 1978, with slowing of the rate increase since 2006 except in men ages 55–64), presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C virus (HCV) infection and nonalcoholic fatty liver disease (NAFLD). In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age greater than 55 years (although there has been an increase in the number of younger cases), Hispanic or Asian ethnicity, family history in a first-degree relative, overweight, obesity (especially in early adulthood), alcohol use (especially in combination with obesity), tobacco use, diabetes mellitus, hypothyroidism (in women), a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. The risk of hepatocellular carcinoma is higher in persons with a viral rather than nonviral cause of cirrhosis and may be increased in persons with autoimmune diseases. Other associations include high levels of HBV replication; HBV genotype C; hepatitis D coinfection; elevated serum ALT levels in persons with chronic hepatitis B (in whom antiviral therapy to suppress HBV replication appears to reduce the risk); HCV genotypes 1b and 3; lack of response to antiviral therapy for HCV infection; hemochromatosis (and possibly the C282Y carrier state); aflatoxin exposure (associated with mutation of the *TP53* gene); alpha-1-antitrypsin deficiency; tyrosinemia; and radiation exposure. In patients with the metabolic syndrome and NAFLD, hepatocellular carcinoma may arise from a hepatocellular adenoma in the absence of cirrhosis. Evidence for an association with long-term use of oral contraceptives is inconclusive. While sulfonylurea and insulin use may increase the risk of hepatocellular carcinoma, consumption of coffee, vegetables, white meat, fish, and n-3 polyunsaturated fatty acids; aspirin use; and statin and metformin use in diabetic patients appear to be protective.

The fibrolamellar variant of hepatocellular carcinoma generally occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, unique genomic profiles, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver. Hepatoblastoma, the most common malignant liver tumor in infants and young children, occurs rarely in adults.

Clinical Findings

A. Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a

cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from a necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. Alpha-fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks and levels are not elevated in patients with fibrolamellar hepatocellular carcinoma); however, mild elevations (10–200 ng/mL [10–200 mcg/L]) are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. Cytologic study of ascitic fluid rarely reveals malignant cells.

C. Imaging

Multiphasic helical CT and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor; MRI may be more sensitive than CT, and imaging with gadoxetic acid increases sensitivity. Lesions smaller than 1 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasonography is less sensitive and more operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasonography has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is thus associated with false-positive results. In selected cases, endoscopic ultrasonography (EUS) may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions smaller than 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions 1 cm or larger, biopsy can be deferred

when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1a: solitary tumor less than or equal to 2 cm; T1b: solitary tumor more than 2 cm without vascular invasion; T2: solitary tumor more than 2 cm with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors with at least one more than 5 cm; T4: single or multiple tumors of any size involving a major branch of the portal or hepatic vein or with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1, regional lymph node metastasis; M1, distant metastasis; F0, no to moderate hepatic fibrosis; F1, severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Pugh class, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

► Screening & Prevention

Surveillance for the development of hepatocellular carcinoma is recommended in patients with chronic hepatitis B (beginning as early as age 20 in Africans, age 40 in Asians or those with a family history of hepatocellular carcinoma, and age 50 in others) or cirrhosis caused by HCV, HBV, or alcohol. There is some evidence that surveillance for hepatocellular carcinoma leads to a survival advantage over clinical diagnosis, but only a minority of cases are detected by surveillance. The standard approach is ultrasonography and alpha-fetoprotein testing every 6 months, although the value of alpha-fetoprotein screening has been questioned because of its low sensitivity. CT and MRI are considered too expensive for screening, but the sensitivity of ultrasonography for detecting early hepatocellular carcinoma is only 63%. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year, and patients with tumors detected by surveillance have a less advanced stage on average and greater likelihood that treatment will prolong survival than those not undergoing surveillance. In a population of patients with cirrhosis, over 60% of nodules smaller than 2 cm in diameter detected on a screening ultrasonography prove to be hepatocellular carcinoma. Mass vaccination programs against HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis B and of hepatitis C in patients with cirrhosis also reduces the subsequent risk of hepatocellular carcinoma, and thus hepatocellular carcinoma is considered a preventable neoplasm. However, hepatocellular carcinoma may still occur after clearance of hepatitis B surface antigen or cure of HCV infection and may reduce the efficacy of treatment for HCV infection.

► Treatment

Surgical resection of a solitary hepatocellular carcinoma may result in cure if liver function is preserved (Child-Pugh class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in

selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor less than 5 cm or three or fewer tumors each less than 3 cm in diameter [Milan criteria]) and in those with expanded (University of California, San Francisco) criteria of one tumor less than or equal to 6.5 cm or three or fewer tumors less than or equal to 4.5 cm. The Extended Toronto criteria include tumor differentiation, cancer-related symptoms, confinement of tumor to the liver, and absence of vascular invasion, without regard to tumor number or size, to determine candidacy for liver transplantation, and appear to predict outcomes as well as the Milan criteria. Patients with stage 2 hepatocellular carcinoma meeting the Milan criteria receive an additional 28 points on their Model for End-Stage Liver Disease (MELD) score after 6 months on the waiting list (see Chapter 16), markedly increasing their chances of undergoing transplantation. However, liver transplantation is often impractical because of the donor organ shortage, and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum alpha-fetoprotein level 1000 ng/mL (1000 mcg/L) or higher, or a MELD score 20 or more have poor posttransplantation survival. In patients with a serum alpha-fetoprotein level greater than 1000 ng/mL (1000 mcg/L), downstaging by locoregional therapy to an alpha-fetoprotein level less than 500 ng/mL (500 mcg/L) improves survival following subsequent liver transplantation. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), TACE with drug-eluting beads, transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. TARE with yttrium-90 has been shown to result in a longer time to progression than TACE. Radiofrequency ablation of, cryotherapy of, microwave ablation of, or injection of absolute ethanol into tumors smaller than 2 cm may prolong survival in patients who are not candidates for resection and have tumors that are accessible; these interventions, as well as stereotactic body radiation therapy, may also provide a “bridge” to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors larger than 2 cm in diameter (but is not effective for those larger than 5 cm) and can be performed after TACE in select cases. Cryoablation may result in slower tumor progression than radiofrequency ablation for tumors that are 3.1–4 cm in diameter. Microwave ablation is being used increasingly and allows shorter treatment times. Stereotactic body radiation therapy is also being used to treat unresectable hepatocellular carcinoma and may be effective in treating lesions larger than those treated with ablation techniques. Sorafenib (an oral

multikinase inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]) prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is standard care in these patients. Regorafenib is another oral multikinase inhibitor that provides a survival benefit for patients whose disease progresses despite sorafenib therapy, and nivolumab is an immune checkpoint inhibitor that has been approved for advanced hepatocellular carcinoma. The modified Response Evaluation Criteria in Solid Tumors (mRECIST) are used to assess treatment response based on tumor shrinkage and viability after locoregional and antiangiogenic treatment. Meticulous efforts at palliative care are essential for patients in whom disease progresses despite treatment or in whom advanced tumors, vascular invasion, or extrahepatic spread are present. Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

► Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related hepatocellular carcinoma, the serum alpha-fetoprotein level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. Some, but not all, studies have reported an unexpectedly high rate of early tumor recurrence in patients who were cured of HCV infection with oral direct-acting antiviral agents, rather than interferon-based therapy. A serum alpha-fetoprotein level greater than or equal to 200 ng/mL (200 milli-international units/mL) or increases of greater than 15 ng/mL/month predict worse outcomes in patients awaiting liver transplantation. In patients who are not eligible for surgery, an elevated serum C-reactive protein level is associated with poor survival. Contrary to traditional opinion, the fibrolamellar variant does not have a better prognosis than conventional hepatocellular carcinoma without cirrhosis.

► When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

► When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

CARCINOMA OF THE BILIARY TRACT

ESSENTIALS OF DIAGNOSIS

- ▶ Presents with obstructive jaundice, usually painless, often with dilated biliary tract.
- ▶ Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- ▶ A dilated gallbladder may be palpable (Courvoisier sign).
- ▶ Diagnosis by cholangiography with biopsy and brushings for cytology.

General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease; the incidence may be decreasing in the United States. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter (particularly with hypoechoic foci on EUS), mucosal calcification of the gallbladder (porcelain gallbladder), anomalous pancreaticobiliary ductal junction, and aflatoxin exposure. Genetic factors include *K-ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be seen on initial presentation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue with no extension beyond serosa (visceral peritoneum) (T2a) or into liver (T2b); T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades two or more extrahepatic organs or structures; N1, metastasis to one to three regional lymph nodes; N2, metastasis to four or more regional lymph nodes; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 10–25% of all hepatobiliary malignancies and 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70, with a slight male

predominance, and more common in Asia. About 50% arise at the confluence of the hepatic ducts (perihilar, or so-called Klatskin, tumors), and 40% arise in the distal extrahepatic bile duct (the incidence of which has risen since 1990); the remainder are intrahepatic (the incidence of which rose dramatically from the 1970s to the early 2000s). Staging for perihilar cholangiocarcinoma is as follows: Tis, carcinoma in situ/high-grade dysplasia; T1, tumor is confined to bile duct; T2, tumor invades beyond the wall of the bile duct to surrounding adipose tissue (2a) or to the adjacent liver (2b); T3, tumor invades unilateral branches of the portal vein or hepatic artery; T4, tumor invades the main portal vein or its branches bilaterally, common hepatic artery, second-order biliary radicals, and contralateral portal vein or hepatic artery; N1, metastasis to one to three regional lymph nodes; N2, metastasis to one to four regional lymph nodes; M1, distant metastasis. Staging for intrahepatic cholangiocarcinoma is as follows: T1a, solitary tumor less than or equal to 5 cm without vascular invasion; T1b, solitary tumor more than 5 cm without vascular invasion; T2, solitary tumor with intrahepatic vascular invasion or multiple tumors 5 cm or smaller with or without vascular invasion; T3, tumor perforating the visceral peritoneum; T4, tumor invades adjacent organ (except gallbladder); N1, regional lymph node metastasis; and M1, distant metastasis. Additional staging is available for distal bile duct tumors. Other staging systems consider the patient's age, performance status, tumor extent and form, perineural invasion, vascular encasement, hepatic lobe atrophy, underlying liver disease, and peritoneal metastasis. The frequency of carcinoma in persons with a choledochal cyst has been reported to be over 14% at 20 years, and surgical excision is recommended. Most cases of cholangiocarcinoma are sporadic. There is an increased incidence of cholangiocarcinoma in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; smoking; and past exposure to Thorotrast, a contrast agent. Aspirin use is associated with a reduced risk of all types of cholangiocarcinoma, and in diabetic patients, metformin use is associated with a reduced risk of intrahepatic cholangiocarcinoma. In Southeast Asia, hepatolithiasis, chronic typhoid carriage, and infection of the bile ducts with helminths (*Clonorchis sinensis*, *Opisthorchis viverrini*) are associated with an increased risk of cholangiocarcinoma. Hepatitis C virus (and possibly hepatitis B virus) infection, cirrhosis, HIV infection, nonalcoholic fatty liver disease, diabetes mellitus, obesity, and tobacco smoking are risk factors for intrahepatic cholangiocarcinoma. Mixed hepatocellular carcinoma-cholangiocarcinoma is a tumor that is being recognized increasingly.

Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia

and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier sign); however, this clinical generalization has been proven to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. The serum CA 19-9 level is elevated in up to 85% of patients and may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis) but is neither sensitive nor specific.

C. Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tract and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice, but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of hepatocellular carcinoma, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either endoscopic retrograde or percutaneous transhepatic cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens for polysomy improve sensitivity. EUS with FNA of tumors, peroral cholangioscopy, confocal laser endomicroscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation, but FNA can result in tumor seeding and is often avoided if the tumor is potentially resectable.

Treatment

In young and fit patients, curative surgery for gallbladder carcinoma may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage I, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Factors predicting shorter survival for intrahepatic cholangiocarcinoma include large tumor size, multiple tumors, lymph node metastasis, and vascular invasion. Adjuvant chemotherapy with capecitabine has been shown to result in superior overall survival compared with no adjuvant therapy. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a longer duration of patency, but they are associated with a higher rate of stent migration and cholecystitis due to occlusion of the cystic duct and are not associated with longer survival. For perihilar tumors, insertion of a unilateral stent rather than bilateral stents may suffice. Plastic stents are less expensive initially, but not in the long term, because they are more prone to occlude than metal ones; they may be considered in patients expected to survive only a few months. Photodynamic therapy in combination with stent placement prolongs survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Endoscopic retrograde cholangiopancreatography (ERCP)-directed radiofrequency ablation, TACE, and TARE are additional emerging options. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy with gemcitabine alone, but the combination of cisplatin and gemcitabine or capecitabine and gemcitabine prolongs survival in patients with locally advanced or metastatic cholangiocarcinoma. Few patients survive for more than 24 months. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II perihilar cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

CARCINOMA OF THE PANCREAS & AMPULLA OF VATER

ESSENTIALS OF DIAGNOSIS

- ▶ Obstructive jaundice (may be painless).
- ▶ Enlarged gallbladder (may be painful).
- ▶ Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

▶ General Considerations

Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. Pancreatic carcinomas account for 2% of all cancers and 5% of cancer deaths. Ampullary carcinomas are much less common. Risk factors for pancreatic cancer include age, tobacco use (which is thought to cause 20–25% of cases), heavy alcohol use, obesity, chronic pancreatitis, diabetes mellitus, prior abdominal radiation, family history, and possibly gastric ulcer and exposure to arsenic and cadmium. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of pancreatic cancer. In diabetic patients, metformin use may reduce the risk of pancreatic cancer slightly, but insulin use and glucagon-like peptide-1-based therapy (eg, sitagliptin) may increase the risk. About 7% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. In 5–10% of cases, pancreatic cancer occurs as part of a hereditary syndrome, including familial breast cancer (carriers of *BRCA-2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (*PSS1* mutation), familial atypical multiple mole melanoma (*p16/CDKN2A* mutation), Peutz-Jeghers syndrome (*STK11/LKB1* mutation), ataxia-telangiectasia (*ATM* mutation), and Lynch syndrome (hereditary nonpolyposis colorectal cancer [*MLH1*, *MSH2*, *MSH6* mutations]). Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin,

glucagon, vasoactive intestinal peptide, somatostatin, growth hormone-releasing hormone, adrenocorticotrophic hormone, and others) or nonfunctional. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because pancreatic cysts are common and may be mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel-Lindau disease) are benign. However, mucinous cystic neoplasms (defined by the presence of ovarian stroma and accounting for 10–45% of cystic pancreatic neoplasms), intraductal papillary mucinous neoplasms (21–33% of cystic pancreatic neoplasms), solid pseudopapillary tumors (less than 5%, primarily in young women), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of pancreatic adenocarcinoma, unless the cystic neoplasm is at least locally advanced.

▶ Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or, when the lesion is in the tail, located in the left upper quadrant. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasional patients (often aged 40 years or older) present with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by a neoplasm (Courvoisier sign), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Mary Joseph's) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proven useful for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis. Plasma chromogranin A levels are elevated in 88–100% of patients with pancreatic neuroendocrine tumors (NETs).

C. Imaging

Multiphase thin-cut helical CT is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT identifies metastases, delineates the extent of the tumor, and allows percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would preclude attempts at surgical resection, but it is used less commonly since the advent of multiphase helical CT. EUS is more sensitive than CT for detecting pancreatic cancer and equivalent to CT for determining nodal involvement and resectability. A normal EUS excludes pancreatic cancer. EUS may also be used to guide FNA for tissue diagnosis, tumor markers, and DNA analysis. ERCP may clarify an ambiguous CT or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography is used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter detected by endoscopy, EUS, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, EUS, and ERCP and features of the cyst fluid on gross, cytologic, and genetic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (greater than 200 ng/mL [200 mcg/L]) and *K-ras* mutations; and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

▶ Staging

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1a: tumor limited to the pancreas, 0.5 cm or less in greatest dimension; T1b: tumor more than 0.5 cm and less than 1 cm; T1c: tumor 1–2 cm; T2: tumor limited to the pancreas, more than 2 cm and less than or equal to 4 cm in greatest dimension; T3: tumor more than 4 cm in greatest dimension; T4: tumor involves the celiac axis, superior mesenteric artery, or common hepatic artery regardless of size; N1: metastasis to one to three regional lymph nodes; N2: metastasis to four or more regional lymph nodes; M1: distant metastasis.

▶ Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes up to 30% of patients with pancreatic carcinoma. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in

4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for cancers strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant chemotherapy with gemcitabine, 5-fluorouracil, or gemcitabine with capecitabine is superior to no adjuvant therapy. Gemcitabine with capecitabine has been found to be superior to gemcitabine alone. The role of adjuvant chemoradiation is controversial but often used in the United States. Neoadjuvant chemotherapy with or without radiation is increasingly being used to downstage patients and in those with resectable cancer. Common chemotherapy regimens for this purpose include FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan, oxaliplatin) and gemcitabine with albumin-bound (nab)-paclitaxel. Chemoradiotherapy downstages about 30% of patients with locally advanced disease to allow resection. When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient's anticipated survival is less than 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent tumor ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with FOLFIRINOX and with the combination of gemcitabine and nab-paclitaxel. In patients who have received prior chemotherapy, 5-fluorouracil and leucovorin in combination with nanoliposomal irinotecan has resulted in improved survival compared with 5-fluorouracil and leucovorin alone. Celiac plexus nerve block (under CT or endoscopic ultrasound guidance) or thoracoscopic splanchinectomy may improve pain control.

Surgical resection is the treatment of choice for NETs, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, chemotherapy, peptide-receptor radionuclide therapy, and chemoembolization. For potentially neoplastic cystic lesions, there is a consensus that asymptomatic incidental pancreatic cysts 2 cm or smaller are at low risk for harboring invasive carcinoma. The cysts may be monitored by imaging tests (MRI) in 1 year and then every 2 years for 5 years and perhaps longer if no changes are observed, with EUS and FNA if a cyst

enlarges to 3 cm and another high-risk feature (dilated main pancreatic duct, presence of a solid component) develops. The optimal approach is uncertain, however, and other guidelines have been proposed.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudo-papillary tumors (which have a 15% risk of malignant transformation), and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be monitored with serial imaging if they (1) are asymptomatic and exhibit benign features; (2) have a diameter less than 3 cm (some authorities recommend a diameter 1.5 cm or smaller, but even lesions 3 cm or larger may be monitored in elderly persons with no other worrisome cyst features); and (3) lack non-enhancing mural nodules, a thick wall, an abrupt change in the caliber of the pancreatic duct with distal pancreatic atrophy, or possibly bile duct dilatation and gallbladder adenomyomatosis. Most such lesions with benign features remain stable on follow-up, but the risk of malignancy persists for at least 10 years. Moreover, the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

► Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and reported 5-year survival rates range from 2% to 5%. From 1980 to 2010, mortality from pancreatic cancer did not decrease, but it may now be starting to improve. Obesity may adversely affect mortality in Western countries. Metformin may improve survival in diabetic patients with pancreatic adenocarcinoma. Tumors of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, or with a genetic syndrome associated with an increased risk of pancreatic cancer, screening with EUS and helical CT or MRI/MRCP should be considered beginning at age 40–45 or 10 years before the age at which pancreatic cancer was first diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

All patients with carcinoma involving the pancreas and the ampulla of Vater should be referred to a specialist.

► When to Admit

Patients who require surgery and other interventions should be hospitalized.

ALIMENTARY TRACT CANCERS

Pelin Cinar, MD, MS

Kenneth R. McQuaid, MD

ESOPHAGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- Progressive dysphagia to solid food.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

► General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. There were an estimated 17,920 new cases of esophageal cancer in 2018. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma is common in Eastern Europe and Asia while adenocarcinoma is more common in North America and most Western European countries. In the United States, **squamous cell carcinoma** is much more common in blacks than in whites. Most (90%) squamous cell carcinomas occur in the distal two-thirds of the esophagus. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. **Adenocarcinoma** is more common in whites. Its incidence is increasing dramatically, and it is now more common than squamous cell carcinoma in the United States. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus. Obesity also is strongly associated with

adenocarcinoma, even after controlling for gastroesophageal reflux.

► Clinical Findings

A. Symptoms and Signs

The majority (50–60%) of patients with esophageal cancer present with advanced, incurable disease. While early symptoms are nonspecific and subtle, over 90% eventually have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheo-esophageal fistula, characterized by coughing on swallowing or by pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal nerve involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, obstructive, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation. Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheo-esophageal fistula such as pneumonia.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeat biopsy may be necessary.

► Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, EUS with guided FNA biopsy of lymph nodes should be performed to evaluate the locoregional stage. EUS is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread in patients

thought to have localized disease after other diagnostic studies, prior to invasive surgery. Bronchoscopy is sometimes required in esophageal cancers above the carina to exclude tracheobronchial extension. Laparoscopy to exclude occult peritoneal carcinomatosis should be considered in patients with tumors at or near the gastroesophageal junction (see Gastric Adenocarcinoma).

► Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

► Treatment

The approach to esophageal cancer depends on the tumor stage, tumor location, patient preference and functional status, and the expertise of the gastroenterologists, surgeons, oncologists, and radiation oncologists. It is helpful to classify patients into two general categories: those with early stage (curable) disease and those with advanced stage (incurable) disease.

A. Therapy for “Curable” Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced clinicians, endoscopic mucosal resection of Tis and T1a cancers achieves equivalent long-term survival with less morbidity (see Barrett Esophagus, Chapter 15). Patients with larger tumors or deeper tumors invasive to the submucosa (T1b) have higher rates of lymph node metastasis. For this reason, an esophagectomy is recommended for those with T1b tumors. Frequent posttreatment endoscopic surveillance is required to ensure no residual or recurrent tumor.

1. Surgery with or without neoadjuvant chemoradiation therapy—There are multiple surgical approaches to the resection of invasive (non-superficial) but potentially “curable” esophageal cancers (stage Ib, II, IIIA, or IIIB). Accepted techniques include en bloc transthoracic excision of the esophagus with extended lymph node dissection, transhiatal esophagogastrectomy (entailing laparotomy with cervical anastomosis), and minimally invasive esophagectomy techniques. Meta-analysis data suggest equivalent oncologic outcomes from minimally invasive esophagectomy and conventional open techniques, although there are fewer postoperative complications and shorter hospital stays with the laparoscopic approach. Removal of at least 15 lymph nodes is recommended for optimal surgical staging in patients who have not received neoadjuvant therapy; the optimal number of lymph nodes

after neoadjuvant therapy is not known though similar lymphadenectomy is recommended by expert guidelines.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. If regional lymph node metastases have occurred (stages IIB and III), the rate of cure with surgery alone is reduced to less than 20%. Meta-analysis of trials comparing neoadjuvant (preoperative) therapy followed by surgery with surgery alone suggests a 13% absolute improvement in 2-year survival with combined therapy. Preoperative (neoadjuvant) chemoradiation therapy is recommended for stage IIA, IIB, and III tumors in fit patients. The preferred neoadjuvant chemotherapy regimen used with radiation is weekly carboplatin plus paclitaxel (Table 39–2). As an alternative, a combination of cisplatin plus 5-fluorouracil may be used along with radiation. When radiation therapy is considered, techniques that are less toxic such as intensity-modulated radiation therapy (IMRT) or proton beam therapy may be considered. Perioperative chemotherapy without radiation is also appropriate for tumors of the gastroesophageal junction based on the randomized, multicenter, phase III MAGIC trial.

2. Chemotherapy plus radiation therapy without surgery—Combined treatment with chemotherapy and radiation is superior to radiation alone and has achieved long-term survival rates in up to 25% of patients. Chemoradiation alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score greater than 2). Chemoradiation alone as definitive, nonsurgical therapy is more likely to achieve short-term and long-term survival in patients with squamous cell carcinoma than in patients with adenocarcinoma. This is especially true for patients with cervical esophageal cancers, which appear similar biologically to head and neck cancers.

3. Supportive care during definitive therapy—Patients with significant tumor obstruction may require local measures such as esophageal stent placement or percutaneous gastric or jejunal tube placement to maintain adequate hydration and nutrition during neoadjuvant chemoradiation or chemotherapy. Multidisciplinary consultation is required to determine the optimal procedure. Consultation with a nutritionist also is appropriate to optimize nutrition perioperatively.

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4b) that is unresectable or distant metastases (M1) (stage IIIC and stage IV). Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and institutional experience. Many patients with advanced disease

may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5).

1. Chemotherapy or chemoradiation—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIC) who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in those patients with metastatic disease who still have good functional status and expected survival of at least several months. Three-drug combinations commonly include a fluoropyrimidine (5-fluorouracil or capecitabine), a platinum drug (cisplatin or oxaliplatin), and either epirubicin or a taxane (docetaxel or paclitaxel) (Table 39–2). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. In patients with metastatic distal esophageal and gastroesophageal junction adenocarcinomas positive for amplification of the *HER2* gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab (see Chapter 17) to chemotherapy is associated with prolonged survival. In addition, ramucirumab, a monoclonal antibody targeting the VEGF receptor-2, demonstrated a survival advantage in patients with adenocarcinoma of the gastroesophageal junction after progression on first-line therapy when used both as monotherapy and in combination with paclitaxel (Tables 39–2 and 39–3).

2. Local therapy for esophageal obstruction—Patients with advanced esophageal cancer often have a poor functional and nutritional status. Radiation therapy alone to the area of esophageal obstruction may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. This can generally be performed in a short course over a few weeks or less but may be complicated by temporary worsening of dysphagia and odynophagia. For patients with frank obstruction or near obstruction, local antitumor therapies may be preferred. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents (alone or followed by radiation). Palliative feeding tube placement may be considered for hydration and nutrition in selected cases if the obstruction is not amenable or if it is refractory to stenting, radiation, or other local therapies. Stents are most commonly used because of their relative ease of placement. Although dysphagia and quality of life are improved, patients seldom can eat normally after stent placement. Complications occur in 20–40% and include perforation, migration, and tumor ingrowth.

► Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement.

Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to a gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic antitumor therapy (stent).
- Patients with curable and resectable disease for whom neoadjuvant therapy may be appropriate (stage IIB or IIIA) should be referred to medical, radiation, and surgical oncologists for consideration of neoadjuvant chemotherapy, chemoradiotherapy, or surgical resection.
- Patients with metastatic disease should be referred to medical and radiation oncologists for consideration of palliative chemotherapy or chemoradiation.
- Patients with metastatic disease and obstructive tumors not amenable to or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for gastric or jejunal tube placement for liquid artificial nutrition. Early referral to palliative care services may improve symptom management in patients with advanced or metastatic disease.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted. Acute complications such as perforation, bleeding, aspiration, or fistula also may require admission.

GASTRIC ADENOCARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Dyspeptic symptoms with weight loss in patients over age 40 years.
- ▶ Iron deficiency anemia: occult blood in stools.
- ▶ Abnormality detected on upper gastrointestinal series or endoscopy.

General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. However, its incidence has declined rapidly over the last 70 years, especially in Western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in *Helicobacter pylori*. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there were an estimated 26,240 new cases and 10,800 deaths in 2018. The incidence is higher in Asian Americans, Hispanics, African Americans, and American Indian/Alaska Natives.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). The incidence of **intestinal-type gastric cancer** has declined significantly, but it is still the more common type (70–80%); it occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to *H pylori*), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic *H pylori* gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to *H pylori*. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection

more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C. **Diffuse gastric cancer** accounts for 20–30% of gastric cancer cases. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, and has a worse prognosis than intestinal-type cancer. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Hereditary diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology, and confers poor prognosis. Many of these families have a germline mutation of E-cadherin *CDH1*, which is inherited in an autosomal dominant pattern and carries a greater than 60% lifetime risk of gastric cancer. Prophylactic gastrectomy should be considered in patients known to carry this mutation.

In addition to the hereditary diffuse gastric cancer, there are other hereditary cancer predisposition syndromes that account for 3–5% of gastric cancers. These include Lynch syndrome, juvenile polyposis syndrome, Peutz-Jeghers syndrome, and familial adenomatous polyposis. There are specific guidelines for how often screening endoscopies should be done for these syndromes (see Chapter 15).

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a favorable prognosis. *HER2* amplification and overexpression is seen in 10–25% of gastric adenocarcinoma cases and is commonly observed in intestinal histology and moderately differentiated disease. The prognostic significance of *HER2* status is uncertain. Testing for microsatellite instability (MSI), deficiency in mismatch repair proteins (dMMR) and PD-L1 is recommended in advanced disease to identify tumors that may respond to immunotherapy. For gastric adenocarcinoma, MSI-H/dMMR is found in 8–16% of cases.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief

from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in less than 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver test abnormalities, particularly elevation of alkaline phosphatase, may be present if there is metastasis to the liver. Circulating tumor markers do not have established clinical validity in screening or diagnosis of gastric cancer. However, when checked serially, tumor markers can assist in monitoring treatment response.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 60 years with new onset of epigastric symptoms (dyspepsia) and young patients with “alarm” symptoms (dysphagia, recurrent vomiting, significant weight loss), especially in immigrants from countries with a high prevalence of gastric cancer. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions.

D. Imaging

Once a gastric cancer is diagnosed, preoperative evaluation with CT of chest and abdomen (including pelvis in females) and EUS is indicated to delineate the local extent of the primary tumor as well as to evaluate for nodal or distant metastases. EUS is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection. PET or combined PET-CT imaging is recommended for detection of distant metastasis.

Screening

Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed there to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening is not recommended in the United States.

► Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria or muscularis mucosa (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the subserosal connective tissue, and T4 invade serosa or adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there is involvement of 1–2, 3–6, or more than 7 regional nodes. M0 signifies the absence of metastatic disease and M1, its presence. Sampling of at least 15 lymph nodes is recommended during surgical staging (see Curative Surgical Resection below). A staging laparoscopy prior to definitive surgery to exclude peritoneal carcinomatosis should be considered in patients with stage T1b or greater disease without radiographic evidence of distant metastases. Pathologic review should include (1) grade of tumor, (2) histologic subtype, (3) depth of invasion, (4) whether lymphatic or vascular invasion is present, and (5) if there is known metastatic disease, the status of HER2 protein expression by immunohistochemistry or fluorescent in situ hybridization or both.

► Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. All gastric ulcers identified at endoscopy should be biopsied to exclude malignancy. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

► Treatment

A. Curative Surgical Resection

Surgical resection is the only therapy with curative potential. Laparoscopic techniques achieve similar outcomes and lower overall complication rates as open gastrectomy. After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in select patients with small (less than 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with EUS. Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable. The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. The ultimate goal of surgery is obtaining negative surgical margins. Vitamin B₁₂ supplementation is required after gastrectomy. For patients with

localized gastric cancer that is resectable, current National Comprehensive Cancer Network (NCCN) treatment guidelines recommend gastrectomy with extended (D1), or modified regional (D2), lymph node dissection and sampling of 15 or more lymph nodes. D2 lymphadenectomy has been shown to improve disease-specific survival, but is associated with increased postoperative mortality.

B. Perioperative Chemotherapy or Chemoradiation

The use of perioperative chemotherapy or adjuvant chemoradiation is associated with improved survival in patients with localized or locoregional gastric adenocarcinoma who undergo surgical resection. The choice of treatment depends on the location and extent of tumor, type of surgery, patient comorbidities and performance status, and institutional experience. Tumors arising in the gastroesophageal junction may be treated following algorithms for esophageal primary tumors. Multidisciplinary treatment decision making involving the surgeon, radiation oncologist, and medical oncologist is imperative.

C. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to “curative” surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, a surgical diversion with gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months. Multiple chemotherapy regimens have demonstrated activity in metastatic gastric adenocarcinoma (Table 39–2). Two-drug combination regimens are preferred for first-line therapy, with most common regimens including a fluoropyrimidine or a taxane agent plus a platinum agent. A three-drug combination of epirubicin or docetaxel plus cisplatin and 5-fluorouracil, or a modification thereof, may be appropriate for first-line treatment in medically fit patients. Addition of trastuzumab (a monoclonal antibody against HER2 receptor) to standard chemotherapy prolonged survival in the subset (approximately 15%) of patients with advanced gastric adenocarcinomas harboring amplification of the HER2. Trastuzumab is not recommended for combination with anthracyclines such as epirubicin due to risk for cardiotoxicity. Of note, addition of lapatinib, a dual tyrosine kinase inhibitor of HER2 and EGFR, to chemotherapy did not result in improvement in overall survival. After progression on first-line chemotherapy, further chemotherapy treatments are associated with better overall survival than supportive care alone. Second-line treatments include ramucirumab, irinotecan, or paclitaxel (Tables 39–2 and 39–3). Ramucirumab is a monoclonal antibody targeting the VEGF receptor-2 and

can be used both as monotherapy and in combination with paclitaxel. In 2017, the FDA approved the immunotherapeutic agent pembrolizumab, a drug that targets lymphocyte PD-L1, for second-line or subsequent therapy for MSI-H or dMMR cancers and for third-line or beyond therapy for PD-L1–positive adenocarcinomas. In Japan, nivolumab is approved for advanced gastric cancers after progression on standard therapies.

► Prognosis

The 5-year survival of gastric carcinoma is approximately 30%. However, 5-year survival in patients who undergo successful curative resection exceeds 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 60% long-term survival. Patients with stage III tumors have a poor prognosis (less than 30% long-term survival) and should be considered for enrollment in clinical trials. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5). Diffuse-type tumors and tumors located in the proximal stomach have a worse prognosis.

► When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron deficiency anemia, melena, or new-onset dyspepsia (especially if aged 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred for endoscopy.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer, including staging laparoscopy if indicated.
- Prior to surgery, patients should be referred to an oncologist to determine the role for perioperative chemotherapy or adjuvant chemoradiation or chemotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome and vitamin B₁₂ deficiency, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of palliative chemotherapy or chemoradiation. Early referral to palliative care services may also be considered for symptom management in patients with advanced and metastatic disease.

► When to Admit

Patients with protracted vomiting, inability to maintain hydration or nutrition, or acute bleeding.

GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- Symptoms of dyspepsia, weight loss, or anemia.
- Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass or infiltrating lesions; diagnosis established by endoscopic biopsy.
- Abdominal CT and EUS required for staging.

► General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread is essential because the prognosis and treatment of primary and secondary gastric lymphomas are different. Primary lymphoma is the second most common gastric malignancy, accounting for 3–5% of gastric cancers. More than 95% of these are non-Hodgkin B-cell lymphomas mainly consisting of either mucosa-associated lymphoid tissue (MALT)-type lymphoma and diffuse large B-cell lymphoma. Gastric T-cell lymphoma, which is associated with HTLV-1 infection, is rare and makes up 7% of primary gastric lymphomas.

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori*

Anandappa G et al. Emerging novel therapeutic agents in the treatment of patients with gastroesophageal and gastric adenocarcinoma. *Hematol Oncol Clin North Am*. 2017 Jun; 31(3):529–44. [PMID: 28501092]

infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

► Clinical Findings & Staging

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. It tends to have horizontal infiltration as opposed to the vertical extension seen in adenocarcinoma. The diagnosis is established with endoscopic biopsy; FNA is not adequate. Since the disease can be multifocal, biopsies of both suspicious and normal-appearing areas are recommended. Biopsy specimens should be tested for *H pylori* and, if positive, for t(11;18) via PCR or FISH. EUS is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy and should be performed for accurate staging, if available. All patients should undergo staging with CT scanning of chest, abdomen, and pelvis. For patients with diffuse large B-cell lymphomas involving the stomach, combination PET-CT imaging, bone marrow biopsy with aspirate, tumor lysis laboratory tests, and hepatitis B and HIV serologies also may be required for staging and treatment planning (see Chapter 13).

► Treatment

Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type that are low-grade and localized to the stomach wall (stage IE) or perigastric lymph nodes (stage IIE₁) have an excellent prognosis. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in approximately 75% of cases of stage IE and approximately 55% with stage IIE low-grade lymphoma. However, 95% of cancers positive for t(11;18) do not respond to antibiotics. Remission may take as long as a year, and relapse occurs in about 2% of cases per year. Restaging with endoscopy and biopsy is recommended 3 months after antibiotic treatment and 3–6 months following radiation therapy. Ultimately, endoscopic surveillance after treatment is recommended every 3–6 months for 5 years to evaluate for recurrence.

In patients whose tumors harbor specific gene translocations, including t(11;18) (API2-MALT1), t(1;14), or t(14;18), rates of remission after *H pylori* eradication are lower, and treatment with radiation may be required. Patients with localized marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy or rituximab, if not a candidate for radiation. Many patients with minimal disease after successful *H pylori* eradication may be observed closely without further therapy.

The long-term survival of low-grade MALT lymphoma for stage I is over 90% and for stage II is 35–65%. Because

of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. Surgery for diffuse large B-cell lymphoma (but not MALT) has been associated with a better prognosis than conservative treatment. Diffuse large B-cell or other higher-grade lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are treated according to stage and subtype of lymphoma (see Chapter 13).

Ikoma N et al. Multimodality treatment of gastric lymphoma. Surg Clin North Am. 2017 Apr;97(2):405–20. [PMID: 28325194]

GASTRIC NEUROENDOCRINE TUMORS

Gastric NETs make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. The majority of NETs are caused by hypergastrinemia and occur in association with either pernicious anemia (75%) (type 1) or Zollinger-Ellison syndrome (5%) (type 2). Type 1 tumors are associated with chronic atrophic gastritis, gastric achlorhydria, and secondary hypergastrinemia. Initial diagnostic workup includes serum gastrin level, upper endoscopy, and EUS. Gastrin level should be obtained 1 week after the patient has stopped taking protein pump inhibitors. For low-grade tumors (ki-67 less than 3% or less than 2 mitoses/10 HPF), somatostatin receptor-based imaging (somatostatin receptor scintigraphy or gallium-68 dotatate PET/CT) should be considered. For high-grade tumors (ki-67 greater than 20% or greater than 20 mitoses/10 HPF), PET/CT is preferred to evaluate the extent of disease.

For patients with hypergastrinemia (suspected of type 1 or type 2 carcinoid), serum vitamin B₁₂ and intrinsic factor antibody levels should be obtained to exclude pernicious anemia. Gastric NETs associated with Zollinger-Ellison syndrome occur almost exclusively in patients with multiple endocrine neoplasia type 1 (MEN 1), in which chromosomal loss of 11q13 has been reported. Gastric NETs caused by hypergastrinemia tend to be multifocal, be smaller than 1 cm, have a low potential for metastatic spread, and thus are unlikely to cause development of the carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by endoscopic surveillance every 6–12 months, or with observation. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. It can be considered in patients with type 1 gastric NETs to reduce recurrence risk and frequency of post-therapy monitoring. Octreotide therapy may be appropriate for patients with underlying gastrinoma and Zollinger-Ellison syndrome. Patients with tumors larger than 2 cm should undergo endoscopic or surgical resection (see Small Intestinal Adenocarcinomas below).

Type 3 gastric NETs arise sporadically, independent of gastrin production, and account for up to 20% of gastric NETs. Most sporadic gastric NETs are solitary, larger than 2 cm, and have a strong propensity for hepatic or pulmonary metastases and thus the carcinoid syndrome at initial presentation. CT or MRI should be obtained to evaluate for

metastatic disease. Localized sporadic NETs should be treated with partial or total gastrectomy and regional lymphadenectomy. Advanced, low-grade gastric NETs can be monitored with serial scans, if asymptomatic. Somatostatin analogs may provide symptomatic relief for patients with functional gastric NETs. Advanced high-grade gastric neuroendocrine carcinomas are treated in a fashion similar to SCLCs.

National Comprehensive Cancer Network. Clinical Practice Guidelines in Oncology. Neuroendocrine tumors. Version 3. June 13, 2017. https://www.nccn.org/professionals/physician_gls/pdf/neuroendocrine.pdf

GASTROINTESTINAL MESENCHYMAL TUMORS

Gastrointestinal mesenchymal tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract, but most commonly in the stomach (60%) and small intestine (30%). Approximately 85–90% of GISTs have mutations in *KIT*. Other mesenchymal tumors, such as leiomyomas, which derive from smooth muscle cells, generally stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms (most commonly bleeding, pain, or obstruction). At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS with guided FNA biopsy is the optimal study for diagnosing gastric mesenchymal tumors and distinguishing them from other submucosal lesions. Percutaneous biopsy may confer risk of bleeding or intra-abdominal seeding. CT of the abdomen and pelvis with contrast, MRI, and PET imaging are useful in the diagnosis and staging. PET imaging also may be useful to monitor response to treatment.

While almost all GISTs have malignant potential, the risk of developing metastasis is increased with tumor size greater than 2 cm, nongastric location, and mitotic index greater than 5 mitoses per 50 high-powered fields. It is difficult to distinguish benign from malignant tumors by EUS appearance or by FNA. But, in general, lesions are more likely benign if they are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on EUS. Resection settles the issue.

Surgery is recommended for all patients with tumors that are 2 cm or larger, increasing in size, have an EUS appearance suspicious for malignancy, or are symptomatic. The management of asymptomatic gastric lesions 2 cm or smaller in size depends on the EUS features. Tumors with high-risk EUS features can be surgically resected. If no high-risk features are noted, endoscopic surveillance can be performed. Because of the low but real long-term risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients. However, other

patients may be monitored with serial endoscopic ultrasonographic examinations or, in select cases, endoscopic resections. After complete surgical resection, GISTs recur within 5 years in over half of patients. The majority of recurrences are within the first 3 years. Adjuvant therapy with the tyrosine kinase inhibitor imatinib delays recurrence and prolongs survival. Adjuvant imatinib is recommended for all high-risk patients for at least 1 year, though the 5-year recurrence-free survival rate is significantly better following 3 years than 1 year of such therapy (65.6% vs 47.9%). After surgical resection, patients should have surveillance with history and physical examination and CT of the abdomen and pelvis every 3–6 months. Neoadjuvant therapy with imatinib may be considered for patients with localized GIST tumors who are deemed to be at high risk for resection because of comorbidities, tumor size, or tumor location. A biopsy is required to confirm the diagnosis of GIST prior to initiation of neoadjuvant imatinib.

Untreated metastatic GIST tumors are aggressive and carry a poor prognosis. Imatinib induces disease control in up to 85% of patients with metastatic disease with a progression-free survival of 20–24 months and median overall survival of almost 5 years. Imatinib-resistant tumors may respond to high-dose imatinib or to sunitinib, another multi-targeted kinase inhibitor that is approved as second-line therapy for metastatic GIST. For patients who have progressive disease after treatment with imatinib and sunitinib, the multi-targeted kinase inhibitor regorafenib can be considered.

MALIGNANCIES OF THE SMALL INTESTINE

1. Small Intestinal Adenocarcinomas

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The incidence is rare, with 10,470 new diagnoses estimated in 2018 in the United States. Overall, prognosis is poor, with 5-year survival of 85% for localized disease, 75% for regional disease, and 42% for distant disease (overall, 27% of patients are stage IV at diagnosis). The management of small intestinal adenocarcinoma is extrapolated from data available for the

management of colon adenocarcinoma. The ampulla of Vater is the most common site of small bowel carcinoma. The incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Periodic endoscopic surveillance to detect early ampullary neoplasms is therefore recommended. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients.

2. Small Intestinal Lymphomas

Lymphomas may arise primarily in the gastrointestinal tract or may involve it secondarily in patients with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the small intestine. There is an increased incidence of small intestinal lymphomas in patients with AIDS, Crohn disease, and those receiving immunosuppressive therapy. The most common histologic subtype is non-Hodgkin extranodal marginal zone (MALT) B-cell lymphoma. Enteropathy-associated T-cell lymphomas appear to be increasing in incidence in the United States. They are associated with the diagnosis of celiac disease. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. Other types of intestinal lymphomas include primary intestinal follicular cell lymphoma, mantle cell lymphoma, and Burkitt lymphoma (see Chapter 13).

Presenting symptoms or signs of primary small bowel lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and bone marrow biopsy are required to determine stage.

Treatment depends on the tumor histologic subtype and stage of disease (see Chapter 13). Surgical resection of primary intestinal lymphoma, if feasible, may be appropriate for localized tumors. In patients with limited disease (stage IE) in whom resection is performed with negative margins, the role of adjuvant chemotherapy is unclear. Locoregional radiation should be considered if surgical margins are positive. Patients with more extensive disease generally are treated according to the tumor histology.

3. Intestinal Neuroendocrine Tumors

ESSENTIALS OF DIAGNOSIS

- ▶ Majority are asymptomatic and discovered incidentally at endoscopy or surgery.
- ▶ Carcinoid syndrome occurs in less than 10%; hepatic metastases are generally present.
- ▶ Risk of metastasis is related to tumor size and location.

General Considerations

Neuroendocrine tumors account for approximately one-third of tumors arising in the small bowel. Gastrointestinal NETs most commonly occur in the small intestine (45%) but are also found in the rectum (20%), appendix (17%), and colon (11%), with the remainder occurring in the stomach (less than 10%; see Gastric Neuroendocrine Tumors above). Carcinoid tumors are well-differentiated tumors that may secrete a variety of hormones, including serotonin, somatostatin, gastrin, and substance P.

Small intestinal carcinoids most commonly arise in the distal ileum within 60 cm of the ileocecal valve. Up to 30% are multicentric. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rates for patients with locoregional and metastatic small bowel carcinoids are approximately 65% and 35%, respectively. The risk of metastatic spread increases when the tumor is 1 cm or larger and when it is larger than 2 cm with invasion beyond muscularis propria. Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are smaller than 1 cm, and 90% are smaller than 2 cm. However, in patients with appendiceal carcinoid tumors larger than 2 cm, approximately 90% develop nodal and distant metastases; right hemicolectomy is recommended in these cases.

Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination and often locally excised by biopsy or snare polypectomy before the histologic diagnosis is known. Endorectal ultrasound is usually recommended to assess the size, presence and depth of invasion, and presence of lymph node metastases. Rectal carcinoids smaller than 1 cm virtually never metastasize and are treated effectively with local endoscopic or transanal excision. Larger tumors are associated with the development of metastasis in 10%. Hence, a more extensive cancer resection operation is warranted in fit patients with rectal carcinoid tumors larger than 1–2 cm or with high-risk features (such as invasion of muscularis propria or evidence of nodal involvement), or both.

Clinical Findings

A. Symptoms and Signs

Most lesions smaller than 1–2 cm are asymptomatic and difficult to detect by endoscopy or imaging studies. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, bleeding, or bowel infarction. Appendiceal and rectal carcinoids usually are small and asymptomatic, but large lesions can cause bleeding, obstruction, or altered bowel habits. **Carcinoid syndrome** occurs in less than 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor

secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectases.

B. Laboratory Findings

Serum chromogranin A (CgA) is elevated in the majority of NETs, although its sensitivity for small, localized carcinoid tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) and platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Because certain foods and medications can interfere with 5-HIAA levels, these should be withheld for 48 hours prior to a 24-hour urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Abdominal CT or enterography may reveal kinking of the bowel, but because the lesion is extraluminal, the diagnosis may be overlooked for several years. Somatostatin receptor scintigraphy (OctreoScan) or gallium Ga-68 DOTATATE PET scan are routinely used in staging and can help identify diseases that may benefit from treatment with somatostatin analogs. Most patients with carcinoid syndrome have liver metastasis on abdominal imaging.

► Treatment & Outcomes

Small intestinal carcinoids generally are indolent tumors with slow spread. Patients with disease confined to the small intestine should be treated with surgical excision. There is no proven role for adjuvant therapy after complete resection. Five-year survival rates for patients with stage I and II disease are 96% and 87%, respectively. In patients with resectable disease who have lymph node involvement (stage III), the 5-year survival is 74%; however, by 25 years, less than 25% remain disease free. Even patients with metastatic disease may have an indolent course with a 5-year survival of 43%.

In patients with advanced disease, therapy historically has been deferred until the patient is symptomatic. Conventional cytotoxic chemotherapy agents do not achieve significant responses in carcinoid tumors and have not been associated with improved outcomes. Radiolabeled somatostatin analogs are used in Europe as another treatment modality for patients with somatostatin-receptor positive advanced carcinoid tumors. FDA approval is anticipated in the United States in 2018. In patients with metastatic disease, surgery should be directed toward palliation of obstructive symptoms or bleeding.

In patients with carcinoid syndrome, the somatostatin analog octreotide, which inhibits hormone secretion from the carcinoid tumor, can be administered subcutaneously three times a day or as a long-acting intramuscular depot

formulation administered monthly. In 90% of patients this results in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, for a median period of 1 year. Thereafter, many patients stop responding to octreotide. In selected patients with refractory carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. Liver-directed therapy (chemoembolization, radioembolization, or surgical debulking) also may provide symptomatic improvement in some patients with hepatic metastases.

4. Small Intestine Sarcoma

Sarcomas constitute approximately 10% of small bowel neoplasms and are commonly found in the jejunum and ileum (and in a Meckel diverticulum, if present). Most arise from stromal tumors (GISTs) that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above). Common symptoms of small intestine sarcoma include pain, weight loss, bleeding, and perforation. As the lesions tend to enlarge extraluminally, obstruction is rare.

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with antiretroviral therapy. It can also occur in the setting of immunosuppression after organ transplant. It is caused by infection with human herpesvirus 8 (HHV8). Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Widespread involvement may be best treated by systemic chemotherapy using single-agent therapy or combinations of pegylated-doxorubicin, paclitaxel, vincristine, bleomycin, or etoposide. Surgery or radiation may be indicated for isolated high-risk lesions.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Personal or family history of adenomatous or serrated polyps or colorectal cancer are important risk factors.
- ▶ Symptoms or signs depend on tumor location.
- ▶ **Proximal colon:** fecal occult blood, anemia.
- ▶ **Distal colon:** change in bowel habits, hematochezia.
- ▶ Diagnosis established with colonoscopy.

General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Colorectal cancer will develop in approximately 4.2% of Americans and has a 5-year survival rate of 65%. In 2018, there were an estimated 140,250 new cases of colorectal cancer in the United States, with an estimated 50,630 deaths. Between 1996 and 2010, its mortality rate has decreased by 46%. During this same period, the percentage of patients 50 years or older who were screened for colorectal cancer increased to 66%. On average, new cases have been falling 3.2% each year over the last 10 years. The colorectal cancer mortality in adults aged 20–54 years increased by 1% annually from 2004 to 2014, although the same trend was not observed in black patients.

Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. The majority of colorectal cancers are thought to arise from malignant transformation of an adenomatous polyp (tubular, tubulovillous, or villous adenoma) or serrated polyp (hyperplastic polyp, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are “advanced” (ie, polyps at least 1 cm in size, adenomas with villous features or high-grade dysplasia, or serrated polyps with dysplasia) are associated with a greater risk of cancer. Approximately 85% of sporadic colorectal cancers arise from adenomatous polyps and have loss of function of one or more tumor suppressor genes (eg, p53, APC, or DCC) due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as *KRAS* and *BRAF* is present in a subset of colorectal cancers with prognostic and therapeutic implications discussed further below.

Approximately 10–20% of colorectal cancers arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions that leads to inactivation of the DNA mismatch repair gene *MLH1*, resulting in

microsatellite instability, and activation of mutations of the *BRAF* gene. Serrated colon cancers have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes (eg, familial adenomatous polyposis) or hereditary non-polyposis colorectal cancer (HNPCC or Lynch syndrome). These conditions are discussed further in Chapter 15.

Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years with a median age of 68 years at the time of diagnosis. For unknown reasons, its incidence is increasing among younger adults between the ages of 20 and 54.

B. Family History of Neoplasia

A family history of colorectal cancer is present in approximately 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. (See Chapter 15 for discussion of inherited polyposis syndromes.) Approximately 6% of the Ashkenazi Jewish population has a missense mutation in the *APC* gene (*APC I1307K*) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member was younger than 45 years when the cancer was diagnosed. Patients with two first-degree relatives have a fourfold increase, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if they were younger than 60 years when the polyp was detected or if the polyp was 10 mm or larger.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 8 years after disease onset in patients with ulcerative colitis and Crohn colitis (see Chapter 15). For this reason,

initiation of surveillance with colonoscopy is recommended at 8–10 years after onset of inflammatory bowel disease symptoms.

D. Dietary and Lifestyle Factors and Chemoprevention in Colorectal Cancer Risk

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective studies have not shown a reduction in colon cancer or recurrence of adenomatous polyps with diets that are low in fat; are high in fiber, fruits or vegetables; or that include calcium, folate, beta-carotene, or vitamin A, C, D, or E supplements.

Low-dose aspirin has been associated with a reduced risk of colorectal adenomas and cancer in multiple studies. A 2016 USPSTF systematic review of controlled trials concluded that prolonged regular use of low-dose aspirin (81 mg/day) is associated with a 40% reduction in colorectal cancer incidence after 10 years and a 33% reduction in colorectal cancer mortality after 20 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), low-dose aspirin should not be routinely administered as a chemopreventive agent without other medical indications. Specifically, the Task Force recommends initiation of low-dose aspirin in patients who are age 50–59 years, who have a greater than 10% 10-year risk of cardiovascular disease events, who are not at increased risk for bleeding, who have a life expectancy of at least 10 years, and who are willing to take the low-dose aspirin daily for at least 10 years (grade B recommendation). The Task Force states that the decision to initiate low-dose aspirin use for the primary prevention of colorectal cancer (and cardiovascular disease) in adults who are age 60–69 years and who have a 10% or greater 10-year cardiovascular disease risk should be an individual one. Persons who are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years are more likely to benefit; persons who place a higher value on its potential benefits than its potential harms may choose to take low-dose aspirin (grade C recommendation). Low-dose aspirin may also be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, its administration does not obviate the need for colonoscopy screening and surveillance.

Retrospective analysis of randomized phase III trial data and a meta-analysis have shown that patients with higher levels of pre- and post-diagnosis physical activity experience reduced colorectal cancer-specific mortality and all-cause mortality. Maintaining a healthy body weight, a healthy diet, and a physically active lifestyle are recommended in colorectal cancer survivors.

E. Other Factors

The incidence and mortality of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is

due to genetic or socioeconomic factors (eg, diet or reduced access to medical care).

Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Screening for Colorectal Neoplasms, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A CBC is obtained to look for evidence of anemia. Elevated liver biochemical tests, particularly the serum alkaline phosphatase, are suspicious for metastatic disease. The serum carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer, but is not appropriate for screening. A preoperative CEA level greater than 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation. The sensitivity of CEA for detection of recurrence ranges from 68% to 82% and its specificity from 80% to 97%. For this reason, CEA is routinely monitored at the time of adjuvant therapy and during postoperative surveillance for patients who had elevated levels before resection.

C. Colonoscopy

Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy permits biopsy for pathologic confirmation of malignancy. In patients in whom the colonoscope is unable to reach the cecum (less than 5% of cases) or when a nearly obstructing tumor precludes passage of the colonoscope, CT colonography examination should be performed.

D. Imaging

Chest, abdominal, and pelvic CT scans with contrast are required for preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography can be performed to detect hepatic metastases. For rectal cancers (generally defined as tumors arising 12 cm or less proximal to the anal verge), pelvic MRI or endorectal ultrasonography is required to determine the depth of penetration of the cancer through the rectal wall (T stage) and perirectal lymph nodes, informing decisions about preoperative (neoadjuvant) chemoradiotherapy and operative management. PET is not routinely used for staging or surveillance in colorectal cancers.

► Staging

The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant therapy.

► Differential Diagnosis

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

► Treatment

A. Surgery

Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. For colon cancer, multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy.

For rectal carcinoma, preoperative (neoadjuvant) chemoradiation with 5-fluorouracil is recommended in all node-positive tumors, and in T3 and greater tumors, due to increased risk of local recurrence (see below). After neoadjuvant therapy, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the clinical approach. In carefully selected patients with small, mobile (less than 4 cm), well-differentiated T1 or T2 rectal tumors that are less than 8 cm from the anal verge, transanal excision may be

considered. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum by either open or laparoscopic surgery reduces local recurrence to 5%. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (eg, leak, dehiscence, stricture) and defecatory complaints (eg, increased stool frequency, and incontinence). With unresectable rectal cancer, the patient may be palliated with a diverting colostomy or placement of an expandable wire stent. Pathology review of colorectal cancers should include testing for mismatch repair proteins for all patients younger than 70 years or with stage II disease. Tumors of patients with metastatic colorectal cancer should also be tested for extended *RAS* and *BRAF* mutations.

B. Systemic Chemotherapy for Colon Cancer

Chemotherapy has been demonstrated to improve overall and tumor-free survival in select patients with colon cancer depending on stage (Table 39–2).

1. Stage I—Because of the excellent 5-year survival rate (approximately 92%), no adjuvant therapy is recommended for stage I colon cancer. The 5-year survival rate of rectal cancer is approximately 87%.

2. Stage II (node-negative disease)—The 5-year survival rate is approximately 87% for stage IIA disease and 63% for stage IIB disease. A significant survival benefit from adjuvant chemotherapy has not been demonstrated in most randomized clinical trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease who are at higher risk for recurrence (perforation; obstruction; close or indeterminate margins; poorly differentiated histology; lymphatic, vascular, or perineural invasion; T4 tumors; or fewer than 12 lymph nodes sampled) may benefit from adjuvant chemotherapy. Patients whose tumors reveal microsatellite instability have a more favorable prognosis and do not benefit from 5-fluorouracil adjuvant therapy.

3. Stage III (node-positive disease)—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all fit patients (Table 39–2). Large, well-designed studies of adjuvant therapy for stage III colon cancer reported a higher rate of disease-free survival at 5 years for patients treated for 6 months postoperatively with a combination of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX) (73.3%) than with 5-fluorouracil and leucovorin (FL) alone (67.4%). Similar benefit was reported for patients treated with oxaliplatin and capecitabine (orally active fluoropyrimidine). The benefit of adding oxaliplatin to 5-fluorouracil has not been demonstrated in patients who are 70 years of age or older.

Randomized controlled trials comparing 3 months with 6 months of adjuvant therapy have confirmed efficacy with 3 months of therapy in patients with low-risk disease (T1-3, N1) with reduced risk of neuropathy; however, 6 months of adjuvant chemotherapy is still recommended for high-risk disease (T4 or N2). The addition of a biologic agent (bevacizumab or cetuximab) to adjuvant chemotherapy does not improve outcomes.

4. Stage IV (metastatic disease)—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and an additional 30% eventually develop metastasis. A subset of these patients has limited disease that is potentially curable with surgical resection. Resection of isolated liver metastases may result in long-term (over 5 years) survival in 35–55% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, radiofrequency or microwave coagulation, embolization, hepatic intra-arterial chemotherapy) may provide long-term tumor control. A subset of patients who have isolated pulmonary metastases may undergo resection with potential cure. The majority of patients with metastatic disease do not have resectable (curable) disease. In the absence of other treatment, the median survival is less than 12 months; however, with current therapies, median survival approaches 30 months. Tumor location has been found to have a potential prognostic importance: median survival rates are 33.3 months for patients with left-sided colon cancers compared to 19.4 months for those with right-sided cancers.

The goals of therapy for patients with metastatic colorectal cancer are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Currently, either FOLFOX (the addition of oxaliplatin to 5-fluorouracil and folinic acid) or FOLFIRI (the addition of irinotecan to 5-fluorouracil and folinic acid) is the preferred first-line treatment regimen for fit patients. For convenience, oral capecitabine (instead of intravenous 5-fluorouracil and leucovorin) can be used in combination with oxaliplatin as it has similar efficacy to 5-fluorouracil; however, combination with irinotecan is not recommended due to increased toxicity (diarrhea). Addition of a biologic agent to combination chemotherapy improves response rates and overall survival and is recommended in the first-line of treatment in suitable patients. Bevacizumab is a monoclonal antibody targeting VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolongs mean survival by 2–5 months compared with either regimen alone. Cetuximab and panitumumab are monoclonal antibodies targeting EGFR. Activating codon 12 and 13 *K-ras* gene mutations downstream of EGFR are present in approximately 35% of patients with metastatic colorectal cancer and are a biomarker for nonresponse to cetuximab and panitumumab, for which reason the use of these agents is restricted to patients with tumors wild-type for *K-ras*. In stage IV patients with *K-ras* wild-type tumors, the addition of panitumumab or cetuximab to FOLFOX or FOLFIRI prolongs survival by approximately 4 months. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation,

or serious bleeding, in up to 5% of patients. EGFR-targeted agents cause an acneiform rash in the majority of patients. Cetuximab is associated with severe infusion reactions in approximately 2–5%.

When disease progresses despite treatment either with FOLFOX or with FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy is switched to the alternate regimen. The novel anti-angiogenic agent, aflibercept, is FDA approved for second-line treatment of colorectal cancer in combination with FOLFIRI. Palliative therapy with cetuximab or panitumumab can benefit patients with *K-ras* wild-type tumors whose disease has progressed after first-line and second-line chemotherapies. Both trifluridine/tipiracil and the multi-targeted kinase inhibitor regorafenib are FDA approved for patients with metastatic, refractory colorectal cancer after progression on standard regimens.

C. Neoadjuvant and Adjuvant Therapy for Rectal Cancer

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local tumor recurrence with surgery alone (approximately 25%) attributed in part to the difficulty of achieving adequate surgical resection margins and to lack of serosal encasement of the rectum. When initial imaging studies suggest stage I disease, surgery may be performed first (see Surgery above). For stage II and III tumors by clinical staging (including endorectal ultrasound or pelvic MRI), preoperative chemoradiation with 5-fluorouracil or capecitabine as a radiation-sensitizing agent improves disease-free survival and decreases pelvic recurrence rate. Preoperative chemoradiation has been shown to be superior to postoperative chemoradiation with lower local recurrence and toxicity rates in the randomized, phase III CAO/ARO/AIO-94 trial. Following surgical resection with total mesorectal excision (see Surgery above), adjuvant 5-fluorouracil-based therapy (generally with the FOLFOX regimen extrapolating from its benefit in patients with similarly-staged colon cancers) is recommended for a total of approximately 6 months of perioperative therapy inclusive of neoadjuvant chemoradiation.

► Follow-Up After Surgery

Patients who have undergone resections for cure are monitored closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. Patients should be evaluated every 3–6 months for 2 years and then every 6 months for a total of 5 years with history, physical examination, and laboratory surveillance, including serum CEA levels if baseline levels are elevated. The NCCN and ASCO guidelines recommend surveillance CT scans of chest, abdomen, and pelvis annually for up to 5 years post-resection in high-risk stage II and all stage III patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively also should undergo colonoscopy within

3–6 months postoperatively to exclude other synchronous colorectal neoplasms. If a colonoscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, proctoscopy surveillance of the low anterior resection anastomotic site may also be performed periodically. New onset of symptoms or a rising CEA warrants investigation with chest, abdominal, and pelvic CT and colonoscopy to look for a new primary tumor or recurrence, or metachronous metastatic disease that may be amenable to curative or palliative therapy. For patients with a rising CEA level with unrevealing CT imaging, a PET scan may be more sensitive for the detection of occult metastatic disease.

Prognosis

The stage of disease at presentation is the most important determinant of 5-year survival in colon cancer: stage I, greater than 90%; stage II, 70–85%; stage III with fewer than 4 positive lymph nodes, 67%; stage III with more than 4 positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases and yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the USPSTF, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of some kind should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost-effective.

It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs. The 2016 USPSTF endorsed screening for colorectal cancer with any of eight different strategies for average-risk adults aged 50–75 years. In the United States, the two most widely used strategies currently are colonoscopy every 10 years or FIT testing annually.

Recommendations for screening from the 2016 USPSTF and 2008 US Multi-Society Task Force (USMSTF) are listed in Table 39–6. Screening is recommended for all men and women ages 50 through 75 years of age who are at average risk for cancer. Some guidelines recommend screening for African Americans beginning at age 45. The potential for

Table 39–6. Recommendations for colorectal cancer screening,¹ including the U.S. Preventive Services Task Force (2016) recommendations² and the US Multi-Society Task Force on Colorectal Cancer (2008) recommendations.²

Average-risk individuals ≥ 50 years old²

- Annual fecal occult blood testing using higher sensitivity tests (Hemoccult SENSa)
- Annual fecal immunochemical test (FIT)
- Fecal DNA test (interval uncertain)
- Flexible sigmoidoscopy every 5 years
- Colonoscopy every 10 years
- CT colonography every 5 years

Individuals with a family history of a first-degree member with colorectal neoplasia³

- Single first-degree relative with colorectal cancer diagnosed at age 60 years or older:** Begin screening at age 40. Screening guidelines same as average-risk individual; however, preferred method is colonoscopy every 10 years.
- Single first-degree relative with colorectal cancer or advanced adenoma diagnosed before age 60 years, or two first-degree relatives:** Begin screening at age 40 or at age 10 years younger than age at diagnosis of the youngest affected relative, whichever is first in time. Recommended screening: colonoscopy every 5 years.

¹For recommendations for families with inherited polyposis syndromes or hereditary nonpolyposis colon cancer, see Chapter 15.

Screening for Colorectal Cancer: US Preventive Services Task Force Recommendation Statement. *JAMA*. 2016 Jun 21;315(23):2564–75.

³American College of Gastroenterology. Guidelines for Colorectal Cancer Screening. *Am J Gastroenterol*. 2009 Mar;104(3):739–50.

harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults above age 75, it may be considered on a case-by-case basis in adults age 76 through 85 years who have excellent health and functional status. In 2017, the USMSTF issued revised, simplified recommendations in which screening tests were placed into three tiers (Table 39–7). For average-risk patients, colonoscopy every 10 years or fecal immunochemical testing (FIT) testing is preferred (Tier 1). Tier 2 tests (CT colonography every 5 years, flexible sigmoidoscopy every 5 years, or fecal FIT-fecal DNA testing every 3 years) and Tier 3 tests (colon capsule every 5 years) may be offered but are considered less suitable due to various disadvantages (discussed below).

Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk; earlier and more frequent screening may be recommended (preferably with colonoscopy) for these individuals. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15. For patients at average

Table 39–7. Revised recommendations for colorectal cancer screening for average-risk individuals from the US Multi-Society Task Force on Colorectal Cancer (2017).¹

Tier 1²
Colonoscopy every 10 years, or Fecal immunochemical test (FIT) every 1 year
Tier 2³
CT colonography every 5 years, or Flexible sigmoidoscopy every 5–10 years, or Fecal FIT-fecal DNA testing every 3 years
Tier 3³
Colon capsule every 5 years

¹Screening of individuals considered to be at “average risk” for colorectal cancer is recommended beginning at 50 years of age, except in African-Americans for whom beginning at 45 years of age is supported by some limited data. Since the incidence of colorectal cancer is rising in persons under age 50 years, a thorough diagnostic evaluation is recommended for younger individuals with rectal bleeding. Colorectal screening can be discontinued at 75 years of age in persons who are up-to-date with screening and who have had consistently negative screening tests (especially prior negative colonoscopy), or in individuals who have life expectancies of less than 10 years. Conversely, in persons who have no prior screening, colorectal screening can be initiated and continued to 85 years of age, depending on health and life expectancy.

²Colonoscopy and FIT are recommended as the cornerstones of colorectal cancer screening. In a sequential approach in which colonoscopy every 10 years is offered first, FIT done annually should be offered to patients who decline colonoscopy. “Tier 1” designation indicates that colonoscopy and FIT are recommended as the tests of choice even when multiple other options are available. A risk-stratified approach is also considered appropriate with FIT screening in patient populations estimated to have a low prevalence of advanced colonic neoplasia and colonoscopy considered more appropriate in patient populations estimated to have a high prevalence of colonic neoplasia.

³Tier 2 and Tier 3 tests may be offered but are considered less suitable due to various disadvantages (see text).

Note: USMSTF screening recommendations vary for individuals considered to be at “high risk” for colorectal cancer: Specifically, for individuals with a family history of colorectal cancer or advanced adenoma in a first-degree relative at age < 60 years or with these findings in two first-degree relatives at any age, screening by colonoscopy every 5 years is recommended, beginning 10 years before the age at diagnosis of the youngest relative or at age 40 years, whichever is earlier. Individuals with a single first-degree relative diagnosed with colorectal cancer or advanced adenoma at age > 60 years are recommended to undertake the “average-risk” screening options shown above but beginning at 40 years of age. Modified, with permission, from Rex DK et al. Colorectal cancer screening: recommendations for physicians and patients from the U.S. Multi-Society Task Force on Colorectal Cancer. *Am J Gastroenterol*. 2017 Jul;112(7):1016–30. By permission from Springer Nature.

risk for colorectal cancer, the recommendations of the USPSTF and USMSTF are discussed below.

Screening tests may be classified into two broad categories: stool-based tests and examinations that visualize the structure of the colon by direct endoscopic inspection or radiographic imaging.

A. Stool-Based Tests

1. Fecal occult blood test—Most colorectal cancers and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based tests (gFOBT) (eg, Hemoccult I and II and Hemoccult SENSa) that detect the pseudoperoxidase activity of heme or hemoglobin and fecal immunochemical tests (FIT) that detect human globin. In clinical trials, FIT have proven superior to gFOBT in sensitivity for detection of colorectal cancer and advanced adenomas with similar specificity. Because FIT are not affected by diet or medications and have superior accuracy, the USMSTF now recommends their use instead of gFOBT.

Several FIT kits are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. In 19 clinical studies, the pooled sensitivity and specificity of FIT for colorectal cancer in average-risk patients were 79% and 94%, respectively. The optimal interval (yearly or every 2 years) and number of stool samples (one or two) required for optimal FIT testing is as yet undetermined. Three randomized controlled trials comparing one-time colonoscopy with FIT testing for colorectal cancer screening are ongoing. Currently, annual testing of a single stool sample is recommended.

FIT testing is the preferred option for population-based screening in various European and Australian programs. In the United States, it is offered as the preferred option by many healthcare plans. For healthcare systems in which screening colonoscopy is readily available, FIT is a suitable option for patients seeking a noninvasive screening test who are willing to undertake annual fecal testing. Patients with a positive FIT test must undergo further evaluation with colonoscopy.

2. Multitarget DNA assay—Stool DNA tests measure a variety of mutated genes and methylated gene markers from exfoliated tumor cells. A newer-generation assay (“Cologuard”) combines a fecal DNA panel with a FIT. In a prospective comparative trial conducted in persons at average risk for colorectal cancer undergoing colonoscopy, the sensitivity for colorectal cancer for “Cologuard” was 92.3% vs 73.8% for FIT alone and the sensitivity for adenomas larger than 1 cm or serrated polyps for “Cologuard” was 42.4% vs 23.8% for FIT alone. A positive stool DNA test requires colonoscopy evaluation. Compared with FIT testing alone, FIT-fecal DNA testing has disadvantages including higher cost, lower specificity, lower cost-effectiveness, cumbersome requirements for stool collection and mailing. Hence, the 2017 USMSTF relegated it to Tier 2, noting that it may be recommended in patients age 50–65 years who seek a noninvasive test with high-sensitivity, due to acceptable specificity in this age group.

B. Endoscopic Examinations of the Colon

1. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of

subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy, with over 60% of US adults screened in the past 10 years. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced colonic neoplasia is 4–11% and of colon cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it has several disadvantages. To allow adequate visualization of the entire colonic mucosa, it requires thorough bowel cleansing the evening and morning prior to the examination. To alleviate discomfort during the procedure, intravenous sedation is used for most patients, necessitating a companion to transport the patient home post-procedure. Serious complications occur uncommonly; they include perforation (0.1%), bleeding (0.25%), and death (2.9/100,000).

The skill of the operator has a major impact upon the quality of the colonoscopy examination. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to polyps and early cancers that were overlooked during the colonoscopy. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon (80%) than the proximal colon (40–60%). This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

2. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon. Therefore, patients with an adenomatous polyp of any size found during screening sigmoidoscopy should subsequently undergo colonoscopy to evaluate the proximal colon. A 2012 US study of almost 155,000 participants randomized to sigmoidoscopy screening or usual care between 1993 and 2001 reported a 50% reduction in distal colorectal cancer mortality in the sigmoidoscopy group after 11 years median follow-up.

The chief disadvantage of screening with flexible sigmoidoscopy is that it requires some bowel cleansing, it may be associated with some discomfort (since intravenous sedation is not used), and it does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in persons older than age 65 years, in

African Americans, and in women. For these reasons, the 2017 USMSTF recommendations have placed flexible sigmoidoscopy among Tier 2 tests. If chosen, flexible sigmoidoscopy should be performed every 5–10 years.

C. Radiographic and Other Imaging of the Colon

1. CT colonography—Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy (virtual colonoscopy). CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is greater than 95% for the detection of cancer and greater than 84–92% for the detection of polyps 10 mm or larger. CT colonography is less sensitive than colonoscopy for the detection of polyps smaller than 1 cm, flat adenomas, and serrated polyps.

Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps 10 mm or larger should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps less than 10 mm in size is controversial. The USMSTF currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps smaller than 6 mm; however, some radiologists choose not even to report these findings.

The chief disadvantages of CT colonography are the need for a bowel preparation, limited availability in many health care systems, a possible increased risk of neoplasia due to radiation exposure, and the potential for finding incidental extracolonic findings that may lead to further evaluations. The 2017 USMSTF has therefore classified this as a Tier 2 screening option (Table 39–7). CT colonography is an excellent screening option in patients who do not wish or are unsuitable for colonoscopy and in patients in whom colonoscopy could not be completed.

2. Capsule colonoscopy—Imaging of the colon can be accomplished by oral ingestion of a capsule that captures video images of the colon. Compared with colonoscopy, the colon capsule has reduced sensitivity for polyps greater than 6 mm (64% vs 84%) and for colorectal cancers (74% vs 100%). At present, it is approved by the FDA for evaluation in patients who are not suitable candidates for colonoscopy or in whom colonoscopy could not evaluate the proximal colon. In addition to its suboptimal sensitivity for neoplasia,

the main disadvantages of capsule colonoscopy are its cost, need for extensive bowel preparation, lack of reimbursement by most insurance carriers, and small risk of small bowel obstruction. For these reasons, the 2017 USMSTF recommendations classified it a Tier 3 screening test, suitable for highly selected patients (Table 39–7).

3. Barium enema—Double-contrast barium enema was previously used as a screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time-consuming and difficult to perform, less comfortable, and less accurate. It can no longer be recommended for routine screening.

When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests (iron deficiency anemia) suggestive of colorectal neoplasia should be referred for colonoscopy.
- Patients with suspected colorectal cancer or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to medical and radiation oncologists preoperatively for neoadjuvant therapy. Patients with stage II, III, or IV colorectal tumors should be referred to a medical oncologist.

When to Admit

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with severe complications of chemotherapy.
- Patients with advanced metastatic disease requiring palliative care.

CARCINOMA OF THE ANUS

The anal canal is lined from its proximal to distal extent by columnar, transitional, and non-keratinized squamous epithelium, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers make up the majority of anal cancers. Anal cancer is increased among people practicing receptive anal intercourse and those with a history of anorectal warts. In over 80% of cases, HPV may be detected, suggesting that this virus is a major causal factor. In a large controlled trial, HPV vaccination of healthy men (16 to 26 years old) who have sex with men decreased the incidence of anal intraepithelial neoplasia by 50%. Women with anal cancer are at increased risk for cervical cancer (which may be due to a field effect of oncogenic HPV infection) and require gynecologic screening and monitoring. Anal cancer is increased in HIV-infected individuals, possibly due to interaction with HPV. HPV vaccine is recommended for boys and girls starting at age 11 or 12, for females aged 13 through 26 years, and in men who have sex with men up to age 26 who have not been previously vaccinated.

Bleeding, pain, and local tumor are the most common symptoms. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes. CT or MRI scans of the abdomen and pelvis are required to identify regional lymphadenopathy or metastatic disease at diagnosis. PET imaging may be used in conjunction.

Treatment depends on the tumor location and histologic stage. Well-differentiated and small (less than 2 cm) superficial lesions of the perianal skin may be treated with wide local excision. Adenocarcinoma of the anal canal is

treated in similar fashion to rectal cancer (see above), commonly by abdominoperineal resection with neoadjuvant chemoradiotherapy and adjuvant chemotherapy. Squamous cancer of the anal canal and large perianal tumors invading the sphincter or rectum are treated with combined-modality therapy that includes external radiation with simultaneous chemotherapy (5-fluorouracil plus mitomycin). Local control is achieved in approximately 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy. Metastatic disease is generally treated with 5-fluorouracil in combination with cisplatin. The 5-year survival rate is 81% for localized tumors and approximately 30% for metastatic (stage IV) disease.

CANCERS OF THE GENITOURINARY TRACT

Maxwell V. Meng, MD, FACS

Charles J. Ryan, MD

PROSTATE CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Prostatic induration on DRE or elevation of PSA.
- ▶ Most often asymptomatic.
- ▶ Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostatic cancer is the most common noncutaneous cancer detected in American men and the second leading cause of cancer-related death in men. In 2018 the United States, an estimated 164,690 new cases of prostate cancer were diagnosed, and 29,430 deaths resulted. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland; few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men aged 60–69 years will have the

disease at autopsy, its incidence increases to 67% in men aged 80–89 years. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (high in North America and European countries, intermediate in South America, and low in the Far East). A 50-year-old American man has a lifetime risk of 40% for latent cancer, 16% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. African-American race, family history of prostatic cancer, and history of high dietary fat intake are risk factors for prostate cancer.

Clinical Findings

A. Symptoms and Signs

Prostate cancer may manifest as focal nodules or areas of induration within the prostate at the time of DRE. However, currently most prostate cancers are detected because of elevations in serum PSA (not DRE findings).

Patients rarely present with signs of urinary retention or neurologic symptoms from epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms. Lymph node metastases can lead to lower extremity lymphedema. Because the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the total volume of prostate tissue. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and identifying recurrence before it becomes clinically evident. As a screening test, PSA will be elevated (greater than 4.0 ng/mL [4.0 mcg/L]) in 10–15% of men. Approximately 18–30% of men with intermediate degrees of elevation (4.1–10 ng/mL [4.1–10 mcg/L]) and between 50% and 70% of men with elevations greater than 10 ng/mL (10 mcg/L) will be found to have prostate cancer. Patients with intermediate levels of PSA usually have localized and therefore potentially curable cancers. Interestingly, approximately 20% of patients who undergo radical prostatectomy for localized prostate cancers have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of disease. Whereas most organ-confined cancers are associated with PSA levels below 10 ng/mL (10 mcg/L), advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL (40 mcg/L). Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made

on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients with urinary retention or with ureteral obstruction due to locally advanced prostate cancers may present with elevations in blood urea nitrogen or serum creatinine. Patients with bony metastases may have elevations in serum alkaline phosphatase or calcium. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portion, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least 10 biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Transrectal ultrasonography has primarily been used for the staging of prostate carcinomas, where tumors typically appear as hypoechoic areas. In addition, transrectal ultrasound-guided, rather than digitally guided, biopsy of the prostate is a more accurate way to evaluate suspicious lesions. Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transrectal ultrasound and associated with modest elevations of PSA (ie, less than 10 ng/mL [10 mcg/L]), need no further imaging.

MRI allows for evaluation of the prostate as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI, although newer multi-parametric MRI techniques may better stage patients considering treatment or, alternatively, active surveillance. MRI-guided biopsy may improve not only overall cancer detection but discovery of clinically relevant disease, and its use in routine clinical practice has increased and continues to evolve. CT plays little role because of its inability to accurately identify or stage prostate cancers, but it can be used to detect regional lymphatic metastases and intra-abdominal metastases.

Conventional **radionuclide (99-technetium) bone scans** are superior to conventional plain skeletal radiographs in detecting bony metastases. Most prostate cancer metastases are multiple and most commonly localized to the axial skeleton. Men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations

in PSA greater than 20 ng/mL (20 mcg/L) should undergo radionuclide bone scan. PET (eg, ^{18}F -sodium fluoride [^{18}F -NaF] PET) and ^{18}F -NaF PET/CT hybrid imaging appear to be more sensitive than conventional bone scans. A high frequency of abnormal scans with ^{18}F -NaF PET/CT resulting from degenerative joint disease, however, has resulted in a reduced enthusiasm for their use. Cross-sectional imaging either by CT or MRI is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for FNA. PET imaging using fluciclovine (Axumin) has been approved for suspected cancer recurrence based on elevated PSA after prior treatment. Small molecules targeting PSMA (prostate-specific membrane antigen) also show significant promise as next-generation imaging agents (eg, ^{18}F -DCFBC (N-[N-[(S)-1,3-dicarboxypropyl]carbonyl]-4- ^{18}F -fluorobenzyl-L-cysteine), a low-molecular-weight radiotracer that targets PSMA).

Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer.

Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

► Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in its mortality rate is controversial. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Prostate cancer detection rates using DRE alone vary from 1.5% to 7%, but unfortunately, most of these cancers are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–8. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone. The Prostate Cancer Prevention Trial provided data demonstrating a significant risk of prostate cancer even in men with PSA less than 4.0 ng/mL (4.0 mcg/L) (Table 39–9) and a web-based calculator has been developed to estimate the risk of harboring both prostate cancer and high-grade cancer (<http://myprostatecancerrisk.com>).

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. These include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (**percent free PSA**), and calculation of changes in PSA over time (**PSA velocity**). Generally, men with PSA free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free

Table 39–8. Screening for prostatic cancer: test performance.

Test	Sensitivity	Specificity	Positive Predictive Value
Abnormal PSA (> 4 ng/mL [mcg/L])	0.67	0.97	0.43
Abnormal DRE	0.50	0.94	0.24
Abnormal PSA or DRE	0.84	0.92	0.28
Abnormal PSA and DRE	0.34	0.995	0.49

DRE, digital rectal examination; PSA, prostate-specific antigen. Modified, with permission, from Kramer BS et al. Prostate cancer screening: what we know and what we need to know. *Ann Intern Med.* 1993 Nov 1;119(9):914–23. Copyright © 1993 American College of Physicians. All rights reserved.

fractions less than 10% have an approximately 50% chance of having prostate cancer. Newer tests, including the Prostate Health Index (PHI) and 4kscore (<https://4kscore.com>), may better identify not only men at greater risk for prostate cancer but those with more aggressive disease. The frequency of PSA testing also remains a matter of debate. The traditional yearly screening approach may not be the most efficient; rather, earlier PSA testing at younger age may allow less frequent testing later as well as provide information regarding PSA velocity. Studies from the Baltimore Longitudinal Study of Aging suggest that men with PSA above the age-based median when tested between 40 and 60 years are at significantly increased risk for subsequent cancer detection over 25 years. Men with lower PSA (0.6 ng/mL [0.6 mcg/L] aged 40–50 and 0.71 ng/mL [0.71 mcg/L] aged 50–60) may require less frequent PSA tests. In addition, men with PSA velocity greater than 0.35 ng/mL (0.35 mcg/L) per year measured 10–15 years before diagnosis had significantly worse cancer-specific

survival compared with those with lower PSA velocity. The NCCN guidelines (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp) for prostate cancer early detection incorporate many of these factors (Figure 39–2). The European Association of Urology (EAU) recommends offering a baseline serum PSA to all men aged 40–45 years and subsequently initiating a risk-adapted strategy.

Two large, randomized trials question the benefit of screening men for prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and DRE during 13-year follow-up. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (3.7 and 3.4 deaths per 10,000 person-years, respectively). Similarly, in the European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, the benefit of PSA screening was minimal with an absolute reduction of 1.28 prostate cancer deaths per 1000 men screened at 13-year follow-up. In 2018, the USPSTF issued a revised (Grade C) recommendation for men aged 55 to 69 years that the decision to undergo periodic PSA-based screening should be an individual one. Before deciding about screening, men should discuss its potential benefits and harms with their clinician, incorporating their own values and preferences in the decision. The revised recommendation acknowledges that, while screening offers some men a small potential benefit of reducing the chance of dying from prostate cancer, many other men will experience potential harms from screening. These include false-positive results that require additional testing and possible prostate biopsy; overdiagnosis and overtreatment; and treatment complications, such as incontinence and erectile dysfunction. In determining whether this service is appropriate in individual cases, the individual patient's family history, race/ethnicity, comorbid medical conditions, values about the benefits and harms of screening and treatment-specific outcomes, and other health needs should be considered. Clinicians should not screen men who do not express a preference for screening. For men age 70 years and older, the USPSTF recommends against PSA-based screening (Grade D recommendation).

Table 39–9. Risk of prostate cancer in men with PSA ≤ 4.0 ng/mL (or mcg/L).

PSA Level (ng/mL [or mcg/L])	Percentage With Prostate Cancer	Percentage With High-Grade ¹ Prostate Cancer
≤ 0.5	6.6	12.5
0.6–1.0	10.1	10.0
1.1–2.0	17.0	11.8
2.1–3.0	23.9	19.1
3.1–4.0	26.9	25.0

¹High-grade cancer was defined as Gleason score ≥ 7. Data from Thompson IM et al. Prevalence of prostate cancer among men with a prostate-specific antigen level ≤ 4.0 ng per milliliter. *N Engl J Med.* 2004 May 27;350(22):2239–46.

▶ Staging

The majority of prostate cancers are adenocarcinomas. Most arise in the peripheral zone of the prostate, though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a “primary” grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a “secondary” grade is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five “grades” are possible. Adding the score of the primary and secondary grades gives a Gleason score from 2 to 10. Gleason score correlates with tumor volume, pathologic stage, and prognosis. There are efforts to validate and disseminate a contemporary, simplified five-grade group system.

¹NCCN guidelines utilize PSA threshold of 1.0 ng/mL in men < 50 years, the 75th percentile range for this age group; the median PSA value for men 40–49 years is 0.6 ng/mL.

▲ **Figure 39–2.** An algorithm for prostate cancer early detection. DRE, digital rectal examination; 5-ARI, 5-alpha-reductase inhibitor; PSAV, PSA velocity (ng/mL/year) calculated on at least three consecutive values over at least an 18- to 24-month. (Based on NCCN guidelines, data from the Baltimore Longitudinal Study on Aging, and Prostate Cancer Prevention Trial.)

► Treatment

A. Active Surveillance

The optimal treatment for patients with clinically localized prostate cancers remains controversial. A survival benefit of treating localized prostate cancer has not been conclusively demonstrated. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. The goal of active

surveillance is to avoid treatment in men who never experience disease progression while recognizing and effectively treating men with evidence of progression. Treatment decisions are made based on stage and cancer grade (Gleason score) as well as the age and health of the patient. Given the observed significant migration to lower stage and grade resulting from screening using PSA testing, active surveillance alone may be appropriate management for selected patients. Such patients included are typically

older with small volume, well-differentiated cancers. Depending on the age and health of the patient, some of these very low-volume, low-grade cancers may never become clinically relevant and can be monitored with active surveillance, which involves serial PSA levels, DREs, and periodic prostate biopsies to reassess grade and extent of cancer. Endpoints for intervention in patients on active surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain an active area of research; nonetheless, they are increasingly accepted by patients and clinicians. Active surveillance, which is distinguished from mere observation, is featured prominently in the 2017 NCCN guidelines and may be the preferred management in most men with very low risk prostate cancer. This approach is increasingly accepted and incorporated in routine clinical practice.

B. Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy and related to pathologic stage. Organ-confined cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for radical prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although the surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

C. Radiation Therapy

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and cancer characteristics. The likelihood of a positive prostate biopsy more than 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the cancer may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. **Three-dimensional conformal radiation** delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of

adverse side effects compared with previous techniques. **Brachytherapy**—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate—can be used as monotherapy in those with low-grade or low-volume malignancies or combined with external beam radiation in patients with higher-grade or higher-volume disease. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

D. Cryosurgery

In cryosurgery, liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. The positive biopsy rate after cryoablation ranges between 7% and 23%.

E. Localized Disease

Although selected patients may be candidates for active surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy of longer than 10 years should be considered for treatment. Newly introduced genomic tests may provide novel information to help guide treatment decisions. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared active surveillance with radical prostatectomy in 695 men with clinically localized and well-differentiated to moderately differentiated cancers. Radical prostatectomy significantly reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The relative reduction in the risk of death at 23 years was 0.56 in the prostatectomy group, with the number needed to treat to avert one death (NNT) = 8 patients; the benefit was largest in men younger than age 65 years (relative risk [RR] = 0.45) and with intermediate-risk prostate cancer (RR = 0.38). Surgery also reduced the risk of metastases in older men (RR = 0.68).

F. Locally and Regionally Advanced Disease

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins and seminal vesicle invasion or androgen deprivation for lymph node metastases). Two randomized clinical trials (EORTC 22911 and SWOG 8794) have demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis of SWOG 8794 showed improved overall survival in men receiving adjuvant radiation therapy. Evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (less than 6 months).

Those with locally extensive cancers, including seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy.

A variety of investigational regimens are being tested in an effort to improve cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone.

G. Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. Most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate

carcinoma will respond to various forms of androgen deprivation. **Androgen deprivation therapy** may be effected at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–10). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves androgen deprivation without orchiectomy and is the most common method of reducing testosterone levels. A single LHRH antagonist (degarelix) is FDA approved and has no short-term testosterone “flare” associated with LHRH agonists. Because of its rapid onset of action, **ketoconazole** should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both

Table 39–10. Androgen deprivation for prostatic cancer.

Level	Agent	Dose	Sequelae
Pituitary, hypothalamus	Diethylstilbestrol	1–3 mg orally daily	Gynecomastia, hot flushes, thromboembolic disease, erectile dysfunction
	LHRH agonists Leuprolide Goserelin Triptorelin Histrelin	Daily subcutaneous injection Monthly to quarterly depot injection Monthly depot injection Annual subcutaneous implant	Erectile dysfunction, hot flushes, gynecomastia, rarely anemia
	LHRH antagonist Degarelix	240 mg subcutaneously initial dose, then 80 mg subcutaneously monthly	Hot flushes, weight gain, erectile dysfunction, increased liver tests
Adrenal	Ketoconazole	400 mg three times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Aminoglutethimide	250 mg four times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Corticosteroid Prednisone	20–40 mg orally daily	Gastrointestinal bleeding, fluid retention
	CYP17a1 inhibitor Abiraterone	1000 mg orally daily (with prednisone 5 mg orally twice daily)	Weight gain, fluid retention, hypokalemia, hypertension
Testis	Orchiectomy		Gynecomastia, hot flushes, erectile dysfunction
Prostate cell	Antiandrogens		
	Flutamide	250 mg three times orally daily	No erectile dysfunction when used alone; nausea, diarrhea
	Bicalutamide	50 mg orally daily	Liver, cardiac and pulmonary toxicity
	Enzalutamide	160 mg orally daily	Seizures, dizziness, asthenia
	Cytotoxic chemotherapeutic agents		Bone marrow, skin, pulmonary, cardiac, gastrointestinal, hepatic toxicities possible
	Docetaxel	75 mg/m ² intravenously once on day 1 of 21-day cycle (with prednisone 10 mg orally daily)	
	Cabazitaxel	20 mg/m ² intravenously once on day 1 of 21-day cycle (with prednisone 10 mg orally daily)	

LHRH, luteinizing hormone-releasing hormone.

testicular and adrenal androgens allows for a better initial and longer response than methods that only inhibit production of testicular androgens. In patients with untreated metastatic disease, **complete androgen blockade**, combining either oral **abiraterone acetate** plus **prednisone** or **docetaxel** plus **prednisone** with use of an LHRH agonist/antagonist or orchiectomy, results in superior survival compared to LHRH agonist/antagonist therapy alone. Nonsteroidal antiandrogen agents may be useful in the setting of the initial treatment of non-metastatic (PSA only) disease. They act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchiectomy alone or of either in combination with an antiandrogen agent showed little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially. In addition to immediate side effects of androgen deprivation, including sexual dysfunction and hot flashes, the chronic suppression of testosterone leads to osteoporosis and risk of fractures, cardiovascular disease and diabetes mellitus, and decreased muscle and increased fat. **Bisphosphonates** can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal-related events. **Denosumab**, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases in patients with castration-resistant prostate cancer.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with castration-resistant prostate cancer, which is defined as progressing disease despite a suppressed (castrate level) of serum testosterone of less than 50 ng/dL. It is also used in conjunction with initial androgen deprivation therapy for patients with untreated high-volume metastatic disease, where it also improves survival. **Abiraterone** (which targets CYP17, a key enzyme in androgen synthesis) and **enzalutamide** (a potent androgen receptor antagonist) have both demonstrated improvement in survival in castration-resistant prostate cancer patients and can be used prior to or following docetaxel. **Sipuleucel-T**, an autologous cellular immunotherapy, is FDA approved in asymptomatic or minimally symptomatic men with metastatic castration-resistant prostate cancer. **Cabazitaxel** is a second-line taxane chemotherapy used in men who have already received docetaxel. **Radium-223 dichloride** is approved for the treatment of men with castration-resistant, symptomatic bone metastases, with significant improvements in both overall survival and time to skeletal-related events (eg, fractures and spinal cord compression).

Prognosis

The likelihood of success of active surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several web-based tools are available (eg, <https://www.mskcc.org/nomograms/>

Table 39–11. The UCSF Cancer of the Prostate Risk Assessment (CAPRA).

Variable	Level	Points
PSA (ng/mL [or mcg/L]) at diagnosis	0–6	0
	6.1–10	1
	10.1–20	2
	20.1–30	3
	> 30	4
Gleason grade, primary/secondary	1–3/1–3	0
	1–3/4–5	1
	4–5/1–5	3
T stage	T1 or T2	0
	T3a	1
% positive biopsies (biopsy cores positive divided by the number of biopsies obtained)	< 34%	0
	≥ 34%	1

prostate). One of the most widely used is the **Kattan nomogram**; it incorporates cancer stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The University of California San Francisco **CAPRA nomogram** (<https://urology.ucsf.edu/research/cancer/prostate-cancer-risk-assessment-and-the-ucsf-capra-score>) uses serum PSA, Gleason score, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence 3 and 5 years after radical prostatectomy (Tables 39–11 and 39–12)

Table 39–12. CAPRA: Probability of freedom from PSA recurrence after radical prostatectomy by CAPRA point total.

CAPRA Score	3-Year Recurrence-Free Survival (%) (95% CI)	5-Year Recurrence-Free Survival (%) (95% CI)
0–1	91 (85–95)	85 (73–92)
2	89 (83–94)	81 (69–89)
3	81 (73–87)	66 (54–76)
4	81 (69–89)	59 (40–74)
5	69 (51–82)	60 (37–77)
6	54 (27–75)	34 (12–57)
7+	24 (9–43)	8 (0–28)

as well as metastasis and prostate cancer-specific and overall survival. The CAPRA nomogram has been validated on large multicenter and international radical prostatectomy and radiation-treated cohorts.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grades 1 and 2) are usually confined within the prostate, whereas large-volume (greater than 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease, and disease recurrence. The most common sites of lymph node metastases are the obturator and internal iliac lymph node chains and of distant metastases, the axial skeleton.

▶ When to Refer

- Refer all patients to a urologist for management of localized disease or active surveillance.
- For metastatic disease, medical oncology should be consulted for consideration of systemic treatments.
- Active surveillance may be appropriate in selected patients with very low-volume, low-grade prostate cancer.
- Localized disease may be managed by active surveillance, surgery, or radiation therapy.
- Locally extensive, regionally advanced, and metastatic disease often require multimodal treatment strategies.

BLADDER CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Gross or microscopic hematuria.
- ▶ Irritative voiding symptoms.
- ▶ Positive urinary cytology in most patients.
- ▶ Filling defect within bladder noted on imaging.

▶ General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3.1:1), and the mean age at diagnosis is 73 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. In the United States, almost all primary bladder cancers (98%) are epithelial malignancies, usually urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

▶ Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer. Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities results from locally advanced cancers or metastases to pelvic lymph nodes.

B. Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria is accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful to detect the disease initially or to detect its recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%), but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis, or response to therapy.

C. Imaging

Bladder cancers may be identified using ultrasound, CT, or MRI as masses within the bladder. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and to stage more advanced lesions.

D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, transurethral prostate biopsies are performed to detect occult disease in the bladder or elsewhere and potentially identify patients at greater risk for cancer recurrence and progression.

► Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent (depth) of bladder wall penetration and the presence of regional or distant metastases.

The natural history of bladder cancer is based on two separate but related processes: cancer recurrence within the bladder and progression to higher-stage disease. Both are correlated with cancer grade and stage.

► Treatment

Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and selective use of intravesical chemotherapy. The subset of patients with carcinoma in situ and those undergoing resection of large, high-grade, recurrent Ta lesions or T1 cancers are good candidates for adjuvant intravesical therapy.

Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) urothelial cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher-stage or bulky tumors in order to improve their surgical resectability.

A. Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, valrubicin, and BCG, the last being the only agent effective in reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancer in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the bladder, uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion avoid the necessity of an external appliance and can be considered in a significant number of patients.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder, bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and it is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

D. Chemotherapy

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–2). The immune checkpoint inhibitor atezolizumab was approved for use in patients with bladder cancer who have progressed despite platinum chemotherapy.

Combination chemotherapy has been used to decrease recurrence rates with both surgery and radiotherapy and to attempt bladder preservation in those treated with radiation. Neoadjuvant chemotherapy appears to benefit all patients with muscle-invasive disease prior to planned cystectomy. Chemotherapy should also be considered before surgery in those with bulky lesions or those suspected of having regional disease. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or local invasion.

E. Immunotherapy

Anti-PDL-1 immunotherapy with atezolizumab is associated with response rates of 25–30% in locally advanced and metastatic bladder cancer. In many cases, however, the responses to therapy are durable. Atezolizumab was approved by the FDA in May 2016 for urothelial cancer. A tumor test for PDL-1 expression, Ventana PD-L1, was also approved; however, PDL-1 expression is not required for treatment with atezolizumab. Additional checkpoint inhibitors have also been approved, including the anti-PD-1 agents pembrolizumab and nivolumab and the anti-PDL-1 agents durvalumab and avelumab (Table 39–2).

Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few low-grade cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in such patients and survival is excellent (81%). Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

When to Refer

- Refer all patients to a urologist. Hematuria often deserves evaluation with both upper urinary tract imaging and cystoscopy, particularly in a high-risk group (eg, older men).
- Refer when histologic diagnosis and staging require endoscopic resection of cancer.
- Metastatic urothelial cancer should be managed by a medical oncologist.

CANCERS OF THE URETER & RENAL PELVIS

Cancers of the ureter and renal pelvis are rare and occur more commonly in patients who have bladder cancer, Balkan nephropathy, or Lynch syndrome, who smoke, who were exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), and who have a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients; flank pain secondary to bleeding and obstruction occurs less commonly. As with bladder cancers, urinary cytology is often positive. The most common signs identified at the time of CT or intravenous urography include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of cancers present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers. Similar to urothelial bladder cancers, use of chemotherapy prior to surgery may improve outcomes.

RENAL CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Gross or microscopic hematuria.
- ▶ Flank pain or mass in some patients.
- ▶ Systemic symptoms such as fever, weight loss may be prominent.
- ▶ Solid renal mass on imaging.

General Considerations

Kidney (renal cell) and renal pelvis carcinomas account for 3.8% of all adult cancers. In 2018 in the United States, it is estimated that approximately 65,340 cases of renal cell carcinoma will be diagnosed and 14,970 deaths will result. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with a number of paraneoplastic syndromes.

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial causes of renal cell carcinoma have been identified (von Hippel–Lindau syndrome, hereditary papillary renal cell carcinoma, hereditary leiomyoma-renal cell carcinoma, Birt–Hogg–Dubé syndrome) and there is an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation), but sporadic carcinomas are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and sarcomatoid).

Clinical Findings

A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was

detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass was found in only 10–15% of patients, and often a sign of advanced disease. Fever occurs as a paraneoplastic symptom. Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Because of the widespread use of ultrasound and CT scanning, renal tumors are frequently detected incidentally in individuals with no urologic symptoms. There has been profound stage migration toward lower stages of disease over the past 10 years, likely due to the increased use of abdominal imaging. However, population mortality rates remain stable.

B. Laboratory Findings

Hematuria is present in 60% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. **Stauffer syndrome** is a reversible syndrome of hepatic dysfunction (with elevated liver tests) in the absence of metastatic disease.

C. Imaging

Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. These scans confirm the character of the mass and further stage the lesion with respect to regional lymph nodes, renal vein, or liver. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated serum alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing the presence and extent of tumor thrombus within the renal vein or vena cava.

Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include renal angiolipomas (fat density usually visible by CT), renal pelvis urothelial cancers (more central location, involvement of the collecting system, positive urinary cytology), renal oncocytomas (indistinguishable from renal cell carcinoma preoperatively), renal abscesses, and adrenal tumors (superoanterior to the kidney).

Treatment

Surgical extirpation is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer are also candidates for partial nephrectomy, while radical nephrectomy is indicated in patients with cancers larger than 7 cm and those in whom partial nephrectomy is not technically feasible. Radiofrequency and cryosurgical ablation are being studied; they likely yield equivalent short-term oncologic outcomes with reduced morbidity in

select patients. Surveillance in selected patients may be warranted, and percutaneous biopsy can provide information regarding histology and grade to help inform the decision.

No effective cytotoxic chemotherapy is available for metastatic renal cell carcinoma. Vinblastine yields short-term partial response rates of 15%. Bevacizumab can prolong time to progression in patients with metastatic disease (see Table 39–2). With biologic response modifiers, such as interferon- α and interleukin-2, partial response rates of 15–20% and 15–35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high-performance status. Patients with metastatic renal cell carcinoma and good performance status who have resectable primary tumors should undergo cytoreductive nephrectomy. Two randomized trials have shown a survival benefit of surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

Several targeted medications, specifically VEGF, Raf-kinase, and mTOR inhibitors, are effective (40–60% response rates) in patients with advanced kidney cancer (Table 39–2). These oral agents, which include sunitinib, pazopanib, cabozantinib, axitinib, and sorafenib, are generally well tolerated and particularly active for clear cell carcinoma. The appropriate timing and combination of these agents, with and without surgery and cytokine therapy, remain to be determined. Sunitinib has been approved for adjuvant use after complete surgical resection in patients with adverse pathological features. The mTOR inhibitors everolimus and temsirolimus are approved for use in patients with prior anti-VEGF therapy, as is the combination of lenvatinib and everolimus. Nivolumab is an approved immunotherapy for treating metastatic disease that has progressed despite antiangiogenic therapy, and the combination with ipilimumab proved superior to sunitinib in previously untreated metastatic renal cell carcinoma. In 2017, the FDA granted breakthrough therapy designation to the combination of the PD-L1 inhibitor avelumab with the VEGF inhibitor axitinib (Table 39–2).

► Prognosis

After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survivals of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50–60% and 0–15% 5-year disease-free survival, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the solitary metastasis results in 5-year disease-free survival rates of 15–30%.

► When to Refer

- Refer patients with solid renal masses or complex cysts to a urologist for further evaluation.
- Refer patients with renal cell carcinoma to a urologic surgeon for surgical excision.
- Refer patients with metastatic disease to an oncologist and urologist.

OTHER PRIMARY TUMORS OF THE KIDNEY

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions less than 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angioembolization to reduce the risk of bleeding.

SECONDARY CANCERS OF THE KIDNEY

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

TESTICULAR CANCERS (Germ Cell Tumors)

ESSENTIALS OF DIAGNOSIS

- ▶ Most common neoplasm in men aged 20–35 years.
- ▶ Patient typically discovers a painless nodule.
- ▶ Orchiectomy necessary for diagnosis.

General Considerations

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: **nonseminomas**, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (less than 1%), and mixed cell types (40%); and **seminomas** (35%). The lifetime probability of developing testicular cancer is 0.3% for an American male.

Approximately 5% of testicular cancers develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is higher for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter its malignant potential but does facilitate routine examination and cancer detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular cancers are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular cancers may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular cancers, while malignant lymphoma is the most common bilateral testicular tumor overall.

Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy

may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), alpha-fetoprotein, and lactate dehydrogenase. Alpha-fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. Lactate dehydrogenase may be elevated with either type of tumor. Liver tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

C. Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

Staging

Testicular cancer is staged using the TNM system created based on extent of cancer in the testis, status of regional lymph nodes, the presence of metastases in distant lymph nodes or other viscera, and serum levels of tumor markers. Based on these features, germ cell tumors can be grouped to assign an overall stage: stage I lesion is confined to the testis; stage II demonstrates regional lymph node involvement in the retroperitoneum; and stage III indicates distant metastasis.

Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large. Testicular lymphoma is discussed below.

Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer cannot be excluded by examination of the testis, radical orchiectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Up to 75% of clinical stage I **nonseminomas** are cured by orchiectomy alone. Selected patients who meet specific criteria may be offered surveillance after orchiectomy. These criteria are as follows: (1) cancer is confined within the tunica albuginea; (2) cancer does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging of the chest and abdomen

shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen.

Stage IIa and IIb **seminomas** (retroperitoneal disease less than 2 cm diameter in IIa and 2–5 cm in IIb) are treated by radical orchiectomy and retroperitoneal irradiation. Retroperitoneal lymph node dissection is being studied as an alternative to radiation for stage IIa and IIb seminoma. Patients with clinical stage I disease are candidates for surveillance, single-agent carboplatin, or adjuvant radiotherapy. Seminomas of stage IIc (greater than 5-cm-diameter retroperitoneal nodes) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 39–2). After chemotherapy, surgical resection of residual retroperitoneal nodes is warranted if the node is greater than 3 cm in diameter and positive on PET scan, since 40% will harbor residual carcinoma.

Postoperative active surveillance by the clinician and patient means patients are followed up every 2–6 months for the first 2 years and every 4–6 months in the third year. For nonseminomas, tumor markers are obtained at each visit, and chest radiographs and abdominal and pelvic CT scans are obtained every 4–6 months. For seminomas, serum tumor markers may be obtained (optional), chest imaging is obtained only as clinically indicated, and abdominal and pelvic CT scans are performed every 3–6 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. Alternatives to surveillance for clinical stage I nonseminoma include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) (see Table 39–2) or retroperitoneal lymph node dissection.

Following orchiectomy, patients with bulky retroperitoneal disease (greater than 5-cm nodes) or metastatic nonseminomas are treated with combination chemotherapy (cisplatin and etoposide or cisplatin, etoposide, and bleomycin) (Table 39–2). If tumor markers normalize and a residual mass greater than 1 cm persists on imaging studies, it is resected because 15–20% will harbor residual cancer and 40% will harbor teratomas. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10%, retroperitoneal teratoma. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, and ifosfamide).

Prognosis

The 5-year disease-free survival for patients with stage I **nonseminomas** (includes all treatments) ranges from 96% to 100%. For low-volume stage II disease, 90% 5-year disease-free survival is expected. The 5-year disease-free survival rates for stage I and IIa **seminomas** (retroperitoneal disease less than 2 cm in diameter) treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchiectomy and chemotherapy.

Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%.

When to Refer

Refer all patients with solid masses of the testis to a urologist or medical oncologist if metastatic disease is suspected.

SECONDARY CANCERS OF THE TESTIS

Secondary cancers of the testis are rare. In men over the age of 50 years, lymphoma is the most common. Overall, it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular cancers. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney.

CANCER COMPLICATIONS & EMERGENCIES

Patricia A. Cornett, MD

Tiffany O. Dea, PharmD

SPINAL CORD COMPRESSION

ESSENTIALS OF DIAGNOSIS

- Complication of metastatic solid tumor, lymphoma, or plasma cell myeloma (formerly multiple myeloma).
- Back pain is most common presenting symptom.

- ▶ Prompt diagnosis is essential because once a severe neurologic deficit develops, it is often irreversible.
- ▶ Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

▶ General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to its vasculature. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

▶ Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in a cancer patient.

B. Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. If the back pain symptom is nonspecific, a whole-body PET scan with ¹⁸F-2-deoxyglucose may be a useful screening procedure. Bone radiographs are neither sensitive nor specific for the evaluation of a cancer patient with back pain. When neurologic findings suggest spinal cord compression, an emergent MRI should be obtained; the MRI should survey the entire spine to define all areas of tumor involvement for treatment planning purposes.

▶ Treatment

Patients with a known cancer diagnosis found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dexamethasone dose is 10–100 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the

impingement and obtain a pathologic specimen; preoperative corticosteroids should not be given since they might induce a tumor response and compromise the pathology results. Patients with solid tumors who have a single area of compression and who are considered candidates for surgery are best treated first with surgical decompression followed by radiation therapy. Better outcomes (ie, improved ability to ambulate and improved bladder and bowel function) occur in patients who undergo surgery followed by radiation therapy than in those who receive radiation alone. If multiple vertebral body levels are involved with cancer, fractionated radiation therapy is the preferred treatment option. Corticosteroids are generally tapered toward the end of radiation therapy. A scoring system exists for patients presenting with spinal cord metastases to identify those with poor survival times who would be best managed with supportive care or single fraction palliative radiation.

MALIGNANT EFFUSIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Occur in pleural, pericardial, and peritoneal spaces.
- ▶ Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- ▶ Half of undiagnosed effusions in patients not known to have cancer are malignant.

▶ General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

▶ Clinical Findings

A. Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites

complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairs both filling and cardiac output and can be life-threatening. Signs of tamponade include tachycardia, muffled heart sounds, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

B. Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

C. Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

► Differential Diagnosis

The differential diagnosis of a malignant exudative pleural or pericardial effusion includes nonmalignant processes, such as infection, pulmonary embolism, heart failure, and trauma.

The differential diagnosis of malignant ascites includes similar benign processes, such as heart failure, cirrhosis, peritonitis, and pancreatic ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

► Treatment

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the development of an effusion is an end-stage manifestation of the cancer. In this situation, decisions regarding management are in large part dictated by the patient's symptoms and goals of care.

A. Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a **large volume thoracentesis**. With some patients, the effusion slowly reaccumulates, which allows for periodic thoracentesis when the patient becomes symptomatic. However, in many patients, the effusion reaccumulates quickly, causing rapid return of shortness of breath. For those patients, two other management options exist. **Chest tube drainage followed by pleurodesis** involves placement of a chest tube that is connected to closed water seal drainage. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry or doxycycline) is injected into the catheter. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the agent throughout the pleural spaces. Occasionally, spontaneous pleurodesis will occur with drainage ceasing and the chest tube can be removed. Pleurodesis will not be

successful if the lung cannot be reexpanded. These patients are better managed with the second option of **placement of an indwelling catheter** that can be drained by a family member or a visiting nurse. This procedure may also be preferable for patients with short life expectancies or for those who do not respond to pleurodesis. Chest tube drainage followed by pleurodesis or placement of an indwelling catheter have essentially equivalent outcomes in terms of cost, relief of symptoms, and other measures of quality of life.

B. Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include prolonged catheter drainage (for several days until drainage has decreased to 20–30 mL/day) or surgical intervention such as a pericardiotomy or pericardiectomy.

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large-volume paracenteses. As the frequency of drainage to maintain comfort can compromise the patient's quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home. For patients with portal hypertension from large hepatic masses, diuretics (such as spironolactone 100 mg with furosemide 20–40 mg orally daily) may be useful to decrease the need for repeated paracentesis.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Usually symptomatic and severe (15 mg/dL [3.75 mmol/L] or more).
- Most common paraneoplastic endocrine syndrome; accounts for most inpatients with hypercalcemia.
- The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and NSCLC. Hypercalcemia is caused by one of three mechanisms: systemic effects of tumor-released proteins, direct osteolysis of bone by tumor, or vitamin D–mediated osteoabsorption.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapid rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free ionized calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), especially if the rise occurs rapidly, sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of symptoms or signs of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

C. ECG

Electrocardiography in hypercalcemia often shows a shortening of the QT interval.

Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–300 mL/h to ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, zoledronic acid, 4 mg intravenously over 15 minutes, or ibandronate 2–4 mg intravenously over 2 hours. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect, but with repeated dosing, it is more often associated with the very uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. However, hypercalcemia can occur in patients with cancers that are unresponsive to

treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include calcitonin and denosumab; corticosteroids can be useful in patients with myeloma and lymphoma. Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be used in patients with severe, symptomatic hypercalcemia; its onset of action is within hours but its hypocalcemic effect wanes in 2–3 days. Denosumab, 120 mg given subcutaneously weekly for 4 weeks followed by monthly administration, is a choice for long-term management of bisphosphonate-refractory hypercalcemia or for patients with kidney dysfunction that precludes use of a bisphosphonate.

HYPERURICEMIA & TUMOR LYSIS SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Complication of treatment-associated tumor lysis of hematologic and rapidly proliferating malignancies.
- ▶ May be worsened by thiazide diuretics.
- ▶ Rapid increase in serum uric acid can cause acute urate nephropathy from uric acid crystallization.
- ▶ Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired, hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules further exacerbating the hyperphosphatemia and hyperkalemia.

Clinical Findings

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage, further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

Treatment

Prevention is the most important factor in the management of TLS. Aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy helps keep urine flowing and facilitates excretion of uric acid and phosphorus. In addition, for patients at moderate risk for developing TLS, eg, those with intermediate-grade lymphomas and acute leukemias, allopurinol should be given before starting chemotherapy at an oral dose of 100 mg/m² every 8 hours (maximum 800 mg/day) with dose reductions for impaired kidney function. Rasburicase 0.1–0.2 mg/kg/day is given intravenously for 1–7 days to patients at high risk for developing TLS, eg, those with high-grade lymphomas or acute leukemias with markedly elevated white blood cell counts (acute myeloid leukemia, white blood cell count greater than 50,000/mcL [50,000/10⁹/L]; acute lymphoblastic leukemia, white blood cell count greater than 100,000/mcL [100,000/10⁹/L]; or chronic lymphocytic leukemia with large lymph nodes [10 cm or larger] or nodes 5 cm or larger accompanied by white blood cell counts greater than 25,000/mcL [25,000/10⁹/L] and treated with venetoclax; or in any patient in whom hyperuricemia develops despite treatment with allopurinol). Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. Systemic bicarbonate infusions to alkalinize the urine is not routinely recommended unless there is accompanying metabolic acidosis. In addition to the hyperuricemia, laboratory values should be monitored following initiation of chemotherapy; elevated potassium or phosphorus levels need to be promptly managed.

When to Refer

Should urinary output drop, serum creatinine or potassium levels rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.

Howard SC et al. Tumor lysis syndrome in the era of novel and targeted agents in patients with hematologic malignancies: a systematic review. *Ann Hematol*. 2016 Mar;95(4):563–73. [PMID: 26758269]

INFECTIONS

Chapters 30 and 31 provide more detailed discussions of infections in the immunocompromised patient.

ESSENTIALS OF DIAGNOSIS

- ▶ In patients with neutropenia, infection is a medical emergency.
- ▶ Although sometimes attributable to other causes, the presence of fever, defined as a single temperature greater than 38.3°C (101°F) or a temperature of greater than 38°C (100.4°F) for longer than 1 hour, must be assumed to be due to an infection.

General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin lymphoma, plasma cell myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Complicating impaired defense mechanisms are the frequent presence of indwelling catheters, impaired mucosal surfaces, and colonization with more virulent hospital-acquired pathogens.

The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for the majority of infections in cancer patients include gram-positive bacteria (coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Corynebacterium*, and streptococci) and gram-negative bacteria (*Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter*). Gram-positive organism infections are more common, but gram-negative infections are more serious and life-threatening. The risk of bacterial infections rises when the neutrophil count is below 500/mcL ($0.5 \times 10^9/L$); the risk markedly increases when the count falls below 100/mcL ($0.1 \times 10^9/L$) or when there is a prolonged duration of neutropenia, typically greater than 7 days.

Clinical Findings

A thorough physical examination should be performed. Routine DREs are generally avoided unless symptoms suggest a rectal abscess or prostatitis. If a DRE is necessary, antibiotics should be administered first. Appropriate cultures (eg, blood, sputum, urine and, if indicated, cerebrospinal fluid) should always be obtained. Two sets of blood cultures should be drawn before starting antibiotics; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

Treatment

Empiric antibiotic therapy needs to be initiated within 1 hour of presentation and following the collection of blood cultures in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient's clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous beta-lactam with anti-*Pseudomonas* activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an intravenous aminoglycoside or fluoroquinolone should be added for “double” gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from *S aureus* catheter infection, intravenous vancomycin can be given empirically. Low-risk patients may be treated with oral antibiotics and even in the outpatient setting. The Infectious Diseases Society of America (IDSA) has published recommendations for such

antibiotic use. These patients must have an expected neutropenic timeframe of 7 days or less and have no comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary problems (infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease), or liver or kidney disease or impairment. A validated risk index, such as the Multinational Association for Supportive Care in Cancer (MASCC) score, may be used to assess a patient for appropriateness of outpatient management. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens.

Antibiotics should be continued until the neutrophil count is rising and greater than 500/mcL ($0.5 \times 10^9/L$) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers and fever resolves.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

PRIMARY CANCER TREATMENT

Patricia A. Cornett, MD

Tiffany O. Dea, PharmD

SYSTEMIC CANCER THERAPY

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy administered and monitored by a medical oncologist or hematologist. Selection of specific drugs or protocols for various types of cancer is usually based on results of clinical trials. Increasingly, newer agents are being identified that target specific molecular pathways. Yet both initial and acquired drug resistance remains a challenge. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cellular proteins (see Table 39–2 for suggested agents for various cancers).

TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. The complexity of treating cancer has increased over the last decade as more drugs, including those with novel mechanisms of action, have been approved by the US Food and Drug Administration (FDA) and introduced into general practice. Drug side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities

Table 39–13. Commonly used supportive care agents.¹

Agent	Indication	Usual Dose	Adverse Effects
Allopurinol (Xyloprim)	Prevent hyperuricemia from tumor lysis syndrome	600–800 mg/day orally	Acute: none Delayed: rash
Dexrazoxane (Zinecard)	Prevent cardiomyopathy secondary to doxorubicin; anthracycline-induced injection site extravasation	10 times the doxorubicin dose intravenously before doxorubicin; 1000 mg/m ² intravenously on days 1 and 2, then 500 mg/m ² intravenously on day 3	Acute: nausea Delayed: myelosuppression, elevated transaminases
Leucovorin	Rescue after high-dose methotrexate; in combination with fluorouracil for colon cancer	10 mg/m ² intravenously or orally every 6 hours; 20 mg/m ² or 200–500 mg/m ² intravenously before fluorouracil; various doses	Acute: nausea, vomiting, diarrhea Delayed: stomatitis, fatigue
Levoleucovorin (Fusilev)	Rescue after high-dose methotrexate; in combination with fluorouracil for colon cancer	7.5 mg intravenously every 6 hours for 10 doses; 100 mg/m ² intravenously before fluorouracil	Acute: nausea, vomiting Delayed: stomatitis, diarrhea
Mesna (Mesnex)	Prevent ifosfamide-induced hemorrhagic cystitis	20% of ifosfamide dose intravenously at 0, 4, and 8 hours; various doses	Acute: nausea, vomiting Delayed: fatigue

(continued)

Table 39–13. Commonly used supportive care agents.¹ (continued)

Agent	Indication	Usual Dose	Adverse Effects
Palifermin (Kepivance)	Prevent mucositis following chemotherapy	60 mcg/kg/day intravenously for 3 days before and 3 days after chemotherapy	Acute: none Delayed: rash, fever, elevated serum amylase, erythema, edema
Pilocarpine (Salagen)	Radiation-induced xerostomia	5–10 mg orally three times a day	Acute: flushing, sweating, nausea, dizziness Delayed: increased urinary frequency, rhinitis
Radium (Ra)-223 dichloride (Xofigo)	Symptomatic bone metastases	50 kilobecquerel/kg (1.35 microCurie/kg) intravenously every 4 weeks for 6 cycles	Acute: nausea, vomiting, diarrhea, peripheral edema Delayed: myelosuppression
Rasburicase (Elitek)	Prevent hyperuricemia from tumor lysis syndrome	3–6 mg intravenously once	Acute: hypersensitivity, nausea, vomiting, diarrhea, fever, headache Delayed: rash, peripheral edema
Bone-Modifying Agents			
Denosumab (Xgeva)	Osteolytic bone metastasis	120 mg subcutaneously every 4 weeks	Acute: nausea Delayed: hypocalcemia, hypophosphatemia, fatigue, osteonecrosis of the jaw
Pamidronate (Aredia)	Osteolytic bone metastasis, hypercalcemia of malignancy	90 mg intravenously every 3–4 weeks; 60–90 mg intravenously, may repeat after 7 days	Acute: nausea Delayed: dyspnea, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity, hypocalcemia
Zoledronic acid (Zometa)	Osteolytic bone metastasis, hypercalcemia of malignancy	4 mg intravenously every 3–4 weeks; 4 mg intravenously once, may repeat after 7 days	
Growth Factors			
Darbepoetin alfa (Aranesp)	Chemotherapy-induced anemia	2.25 mcg/kg subcutaneously weekly; 500 mcg subcutaneously every 3 weeks	
Epoetin alfa (Epogen, Procrit)	Chemotherapy-induced anemia	40,000 units subcutaneously once weekly; 150 units/kg subcutaneously three times a week	Acute: injection site reaction Delayed: hypertension, thromboembolic events, increased risk of tumor progression or recurrence
Filgrastim (Neupogen)	Febrile neutropenia prophylaxis, mobilization of peripheral stem cells	5–10 mcg/kg/day subcutaneously or intravenously once daily, treat past nadir	Acute: injection site reaction Delayed: bone pain
Pegfilgrastim (Neulasta)	Febrile neutropenia prophylaxis	6 mg subcutaneously once per chemotherapy cycle	
Sargramostim (Leukine)	Myeloid reconstitution following bone marrow transplant, mobilization of peripheral blood stem cells	250 mcg/m ² intravenously daily until the absolute neutrophil count is > 1500 cells/mcL for 3 consecutive days	Acute: fever, rash, pruritus, nausea, vomiting, diarrhea, injection site reaction, dyspnea Delayed: asthenia, bone pain, mucositis, edema, arrhythmia

¹For amifostine, samarium, strontium, filgrastim-sndz, and tbo-filgrastim, see Table 39–13 in *CMDT Online* at www.accessmedicine.com.

Table 39–14. A common scheme for dose modification of cancer chemotherapeutic agents.

Granulocyte Count (cells/mcL)	Platelet Count (/mcL)	Suggested Drug Dosage (% of Full Dose)
> 2000	> 100,000	100%
1000–2000	75,000–100,000	50%
< 2000	< 50,000	0%

of individual drugs are listed in Tables 39–3 and 39–13. Decisions on dose modifications for toxicities should be guided by the intent of therapy. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible.

A CBC including a differential count, with absolute neutrophil count and platelet count, and liver and kidney tests should be obtained before the initiation of chemotherapy. In patients with normal CBCs as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A CBC with differential may be checked at mid cycle (to determine the nadir of the absolute neutrophil and platelet counts), and liver and kidney function tests should be obtained immediately before the next cycle of chemotherapy.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–14.

1. Bone Marrow Toxicity

A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (eg, filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24 hours after cytotoxic chemotherapy is completed, reduces the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 39–13). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with G-CSF when there is at least a 20% risk of febrile neutropenia or when age, medical history, and disease characteristics put the patient at high risk for complications related to myelosuppression.

B. Anemia

Erythropoiesis-stimulating agents (ESAs) ameliorate the anemia and its associated symptoms caused by cancer chemotherapy but these drugs have untoward effects, including an increased risk of thromboembolism, and possibly a decreased survival due to cancer-related deaths as well as a shortened time to tumor progression. The NCCN recommends that these drugs should not be used when the intent

of chemotherapy is curative. Administration of red blood cell transfusions is the alternative to managing symptomatic anemia in such patients.

ESAs can be an option in cancer patients with symptomatic anemia undergoing palliative treatment; patient preference is important in determining when to use ESAs or transfusions. When using ESAs, treatment should not be initiated until the hemoglobin is less than 10 g/dL (100 g/L) and the ESA held when the hemoglobin is greater than 12 g/dL (120 g/L). Epoetin alfa can be given subcutaneously at a dose of 40,000 units weekly or 150 units/kg three times weekly with a target hemoglobin of 11–12 g/dL (110–120 g/L). Darbepoetin alfa is given subcutaneously at a dose of 300–500 mcg every 3 weeks or 2.25 mcg weekly with the same target hemoglobin (see Table 39–13). To have maximum therapeutic effect, patients need to be iron replete. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy.

C. Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving chemotherapy-related thrombocytopenia; however, it is rarely used due to the side effects of fluid retention, heart failure, and arrhythmias. Two drugs that activate the thrombopoietin receptor, romiplostim and eltrombopag, are FDA approved for use in idiopathic thrombocytopenia; while these agents have been used in selected cases of refractory chemotherapy-related thrombocytopenia with some reports of success, trials to date have not demonstrated efficacy in patients with chemotherapy-induced thrombocytopenia and neither agent is FDA approved for this indication.

2. Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced nausea and vomiting is mediated in part by the stimulation of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 (5HT₃) and neurokinin subtype 1 (NK₁). Chemotherapy-induced nausea and vomiting can be anticipatory, occurring even before chemotherapy administration; acute, occurring within minutes to hours of chemotherapy administration; or delayed until the second day and lasting up to 7 days. Chemotherapy drugs are classified into high, moderate, low, and minimal likelihoods of causing emesis (90%, 30–90%, 10–30%, less than 10%, respectively). Highly emetogenic chemotherapy drugs include carmustine, cisplatin, cyclophosphamide (at doses over 1.5 g/m²), dacarbazine, mechlorethamine, and streptozocin, or a combination of regularly dosed anthracyclines and cyclophosphamide. Moderately emetogenic chemotherapy drugs include alemtuzumab, azacitadine, bendamustine, carboplatin, clofarabine, crizotinib, cyclophosphamide, cytarabine, daunomycin, doxorubicin, epirubicin, idarubicin, ifosfamide, irinotecan, mitotane, oxaliplatin, romidepsin, temozolomide, and vismodegib. Low emetogenic drugs include bortezomib, brentuximab, capecitabine, cabozantinib, dabrafenib, dasatinib, docetaxel,

erlotinib, etoposide, fludarabine, fluorouracil, gemcitabine, hydroxyurea, ipilimumab, ixabepilone, lenalidomide, methotrexate, mitomycin, mitoxantrone, omacetaxine, paclitaxel, pemetrexed, pomalidomide, ponatinib, temsirolimus, trametinib, and topotecan. Drugs with minimal risk of emesis include bevacizumab, bleomycin, cetuximab, cladribine, decitabine, fludarabine, nivolumab, panitumumab, pembrolizumab, rituximab, temsirolimus, trastuzumab, vinblastine, vincristine, and vinorelbine.

Major advances have occurred in the development of highly effective antiemetic drugs. Antagonists to the $5HT_3$ -receptor include ondansetron, granisetron, dolasetron, and palonosetron, as well as tropisetron and ramosetron (neither yet available in the United States). Ondansetron can be given either intravenously (8 mg or 0.15 mg/kg) or orally (24 mg once before highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given once as an oral 100-mg dose. Palonosetron, a long-acting $5HT_3$ with high affinity for the $5HT_3$ -receptor, is given once at a dose of 0.25 mg intravenously, both for acute and delayed emesis. Where available, tropisetron is given at a dose of 5 mg either orally or intravenously and ramosetron, as a one-time 300-mcg dose intravenously. The efficacy of the $5HT_3$ -blockers is improved by adding dexamethasone 10 mg once intravenously, then 4 mg orally or intravenously every 6 hours. As a class of drugs, the $5HT_3$ -receptor antagonists have the potential to cause electrocardiogram changes, including QT prolongation. Before using these agents, hypokalemia or hypomagnesemia should be corrected. In addition, clinicians should be cautious when using these agents in patients who are elderly, who have preexisting bradyarrhythmias or heart failure, or who are taking medications known to prolong the QT interval.

Aprepitant, fosaprepitant, and rolapitant are antagonists to the NK_1 receptor. Aprepitant is given as a 125-mg oral dose followed by an 80-mg dose on the second and third day along with a $5HT_3$ -receptor antagonist (such as ondansetron or granisetron) and dexamethasone to increase its immediate and delayed protective effect for highly emetogenic chemotherapy. Fosaprepitant, the intravenous formulation of aprepitant, can be given at a dose of 115 mg if followed by 2 days of aprepitant or at a dose of 150 mg if given alone. Rolapitant, a potent selective NK_1 receptor antagonist, has a 7-day half-life; it is given as a one-time oral dose of 180 mg 1–2 hours before the start of moderately or highly emetogenic chemotherapy.

The first antiemetic combination treatment netupitant/palonosetron (NEPA) is a single-dose capsule consisting of a combination of the new N -receptor antagonist, netupitant 300 mg, and the $5HT_3$ -receptor antagonist, palonosetron 5 mg.

Thus, for highly emetogenic chemotherapy (eg, cisplatin), patients should be offered a four-drug regimen (a $5HT_3$ -antagonist, dexamethasone, neurokinin-1 receptor antagonist, and olanzapine), all given on the first day (and if used, aprepitant given again on the second and third days with decadron and olanzapine continued on days 2–4. For moderately emetogenic chemotherapy, standard regimens

include both three-drug regimens (an NK_1 receptor antagonist, a $5HT_3$ -antagonist, and dexamethasone) or a two-drug combination ($5HT_3$ -antagonist and dexamethasone). Palonosetron is the preferred $5HT_3$ -blocker due to its greater affinity for the $5HT_3$ -receptor and its longer half-life. For low emetogenic chemotherapy drugs, a single agent such as a $5HT_3$ -antagonist or prochlorperazine or dexamethasone can be given. A 25-mg suppository form of prochlorperazine may be used for patients unable to swallow oral medications. Other medications that are helpful for anticipatory or refractory nausea and vomiting are olanzapine, 10 mg given orally once, or lorazepam, 0.5–1.0 mg given orally every 6–8 hours.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild mouth soreness to frank ulcerations. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from mild symptoms of loose stools to life-threatening diarrhea leading to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-fluorouracil, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for oral mucositis include pretreatment dental care, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical antifungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Other strategies for prevention of oral mucositis include the use of the recombinant keratinocyte growth factor inhibitor, palifermin. Prophylaxis with intravenous palifermin (60 mcg/kg/day) for patients receiving high-dose chemotherapy can reduce the incidence and duration of mucositis (Table 39–13).

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors (dasatinib, imatinib, nilotinib, regorafenib, sorafenib, sunitinib) and epithelial growth factor inhibitors (cetuximab, erlotinib, panitumumab). Mild to moderate diarrhea can be managed with oral antidiarrheal medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, severe diarrhea will cause dehydration, electrolyte imbalances, and acute kidney injury; these patients require inpatient management with aggressive intravenous hydration and electrolyte replacement. Octreotide, 100–150 mcg subcutaneously three times daily, can be useful.

4. Skin Toxicity

Dermatologic complications from cancer chemotherapy can include hyperpigmentation (busulfan, hydroxyurea, liposomal doxorubicin), alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema (hand-foot syndrome), most commonly associated with administration of capecitabine, fluorouracil, and liposomal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering, desquamation, and ulceration in its worst forms. Strategies for prevention of acral erythema include oral pyridoxine, 200 mg daily, and applying cold packs to the extremities during chemotherapy administration. Agents targeting the epidermal growth factor pathway can cause an acne-like rash; the development of the rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

5. Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs are summarized in Tables 39–3 and 39–13; however, several of these warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency of urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. The neutralizing agent, mesna, can be used for patients in whom cystitis develops. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented (Table 39–13).

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these types. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop as a form of trigeminal or glossopharyngeal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (docetaxel and paclitaxel) and agents to treat myeloma (bortezomib and thalidomide) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually, though, the development of moderate to severe paresthesias or motor impairment results in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on mild cathartics and other agents (Table 15–4); otherwise, severe impaction may result from an atonic bowel. More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. Methotrexate is almost entirely eliminated by the kidney. Methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated serum liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m² or more given over 4–36 hours, would be lethal without “rescue” of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (less than 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. The dose used in intrathecal therapy is 12 mg. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot clear the drug normally or in patients with effusions in which the drug distributes itself and leaks out continuously, exposing normal tissue to the drug. In a patient with kidney disease or an effusion, prolonged rescue with leucovorin is necessary.

Vigorous hydration and bicarbonate loading can help prevent crystallization of high-dose methotrexate in the renal tubular epithelium and consequent nephrotoxicity. Daily monitoring of the serum creatinine is mandatory.

If possible, drugs impairing methotrexate excretion, such as aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa, should be stopped before methotrexate administration.

D. Cardiotoxicity From Anthracyclines and Other Chemotherapy Drugs

A number of cancer chemotherapy drugs are associated with cardiovascular complications including traditional drugs such as anthracyclines as well as new targeted agents. The anthracycline drugs, including doxorubicin, daunomycin, epirubicin, and idarubicin, can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because it is the most commonly administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated radionuclide cardiac scan (MUGA) to calculate the left ventricular-ejection fraction (LVEF). If the LVEF is greater than 50%, anthracyclines can be administered; if the LVEF is less than 30%, these drugs should not be given. For patients with intermediate values, anthracyclines can be cautiously given, if necessary, at lower doses with LVEF monitoring between doses. Changes in cardiac dynamics occur in most patients by the time they have received a total dose of 300 mg/m² of doxorubicin. In general, patients should not receive doses in excess of 450 mg/m²; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at total dosage levels above 550 mg/m². At lower doses (eg, 350 mg/m²), the symptoms and signs of cardiac failure generally respond well to medical therapy and discontinuation of the anthracycline. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes in other cancers as a substitute for the conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

As molecular mechanisms for cancer have been increasingly delineated, therapies have been developed that better target these mechanisms. Therapies targeting oncogenesis pathways include (1) HER2 inhibitors (lapatinib, pertuzumab, trastuzumab); (2) VEGF signaling pathway inhibitors (afibercept, axitinib, bevacizumab, carozantinib, lenvatinib, pazopanib, ramucirumab, regorafenib, sorafenib, sunitinib, vandertanib); (3) multitargeted tyrosine kinase inhibitors (dasatinib, nilotinib, ponatinib); (4) proteasome inhibitors (bortezomib, carfilzomib); and (5) immune checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab). Many of the pathways targeted by these drugs share a common biologic pathway in cardiac tissue.

Untoward cardiac events are being increasingly reported with these agents, including arrhythmias, cardiac ischemia, myocarditis, thrombosis, and heart failure. It is important to carefully monitor patients on these drugs and aggressively manage any modifiable cardiac risk factors (smoking, hyperlipidemia, diabetes mellitus, sedentary lifestyle).

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating testicular, bladder, head and neck, lung, and ovarian cancers. With cisplatin, the serious side effects of nephrotoxicity and neurotoxicity must be anticipated and aggressively managed. Patients must be vigorously hydrated prior to, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low serum magnesium, potassium, and sodium levels can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m². Ototoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. Amifostine, given intravenously at a dose of 910 mg/m² over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not appear to compromise its antineoplastic effect. The second-generation platinum analog, carboplatin, is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

F. Bleomycin Toxicity

See online text at www.accessmedicine.com/cmdt.

PROGNOSIS

Patients receiving chemotherapy for curative intent will often tolerate side effects with the knowledge that the treatment may result in eradication of their cancer. Patients receiving therapy for palliative intent often have their therapy tailored to improve quality of life while minimizing major side effects. A valuable sign of clinical improvement is the general well-being of the patient. Although general well-being is a combination of subjective (possibly partly a placebo effect) and objective factors, it nonetheless serves as a sign of clinical improvement along with improved appetite and weight gain and increased "performance status" (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5).

ACUTE INTERMITTENT PORPHYRIA

ESSENTIALS OF DIAGNOSIS

- ▶ Unexplained abdominal crisis, generally in young women.
- ▶ Acute peripheral or central nervous system dysfunction; recurrent psychiatric illnesses.
- ▶ Hyponatremia.
- ▶ Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant condition, though it remains clinically silent in most patients who carry a mutation in *HMBS*. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of hydroxymethylbilane synthase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute

abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, altered consciousness, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have different mutations in *HMBS* causing AIP. Mutations can be detected in 90% of patients and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1 and on the internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose in saline and hematin. A minimum of 300 g of carbohydrate per day

Table 40–1. Some of the “unsafe” and “probably safe” drugs used in the treatment of acute porphyrias.

Unsafe	Probably Safe
Alcohol	Acetaminophen
Alkylating agents	Amitriptyline
Barbiturates	Aspirin
Carbamazepine	Atropine
Chloroquine	Beta-adrenergic blockers
Chlorpropamide	Chloral hydrate
Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam
Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscine
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyldopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spiroglactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouracil
Theophylline	
Tolazamide	
Tolbutamide	
Valproic acid	

should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

▶ When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

▶ When to Admit

The patient should be hospitalized for an acute attack when accompanied by mental status changes, seizure, or hyponatremia.

DOWN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- ▶ Intellectual disability.
- ▶ Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- ▶ Alzheimer dementia in early-to-mid adulthood.
- ▶ Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

▶ General Considerations

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700, but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for alpha-fetoprotein and other biomarkers (“multiple marker screening”) and by detecting increased nuchal thickness and underdevelopment of the nasal bone on ultrasonography. Prenatal diagnosis with high sensitivity and specificity can be achieved by assaying fetal DNA that is circulating in maternal blood. The chance of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. Because there are so many distinct conditions, though, the chance of fathering an offspring with any given one is extremely small.

Clinical Findings

A. Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrio-ventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, frequent infections due to immune deficiency, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

B. Laboratory Findings

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent's relatives.

Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. Effective treatment does no long-term harm to neurodevelopment. As yet, no medical treatment has been proven to affect the neurodevelopmental or the neurodegenerative aspects. Based on the glutamatergic hypothesis for Alzheimer disease, studies have been initiated examining the potential benefit of the *N*-methyl-D-aspartate receptor antagonist memantine.

When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

When to Admit

A young patient should be hospitalized for failure to thrive, regurgitation, or breathlessness.

FAMILIAL HYPERCHOLESTEROLEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Elevated serum total cholesterol and LDL cholesterol.
- ▶ Autosomal dominant inheritance.
- ▶ Mutation in *LRL*, *PCSK9*, or *APOB*.

General Considerations

Familial hypercholesterolemia (FH) is a group of autosomal dominant conditions that result in elevated low-density lipoprotein (LDL) levels in the blood. High LDL predisposes to atherosclerosis, which in turn leads to premature myocardial infarction or stroke. The incidence of these serious complications increases with age and when associated with the other common predispositions to atherosclerosis, such as smoking and hypertension. About 1 in 500 people in the United States have FH, and worldwide prevalence is about 10 million. Only about 15% of people with FH are diagnosed and even fewer are treated effectively.

In the great majority of instances, the elevated LDL is inherited as an autosomal dominant trait; each child of an affected parent has a 50/50 chance of inheriting FH. In uncommon cases, both parents have a mutation in the LDL receptor and one-quarter of their children, on average, will inherit two mutant alleles and have homozygous FH, which is a much more serious disease with manifestations in childhood.

Mutations in the following genes can cause FH: (1) *LDLR*, which encodes the LDL receptor located on the surface of cells and is responsible for moving LDL into the cell for metabolism; the most common mutant gene in FH; (2) *APOB*, which encodes a component of LDL and mutations inhibit binding to the LDL receptor; (3) *PCSK9*, which encodes a protein that normally reduces production of LDL receptors, so mutations actually protect from hypercholesterolemia; and (4) *ARH*, which requires mutations in both alleles (autosomal recessive inheritance) to cause FH.

Clinical Findings

A. Symptoms and Signs

Yellow lipid deposits appear on tendons, especially the Achilles (tendon xanthoma).

B. Laboratory Findings

The total serum cholesterol is elevated with the LDL component particularly high. A detailed family history and genetic testing are recommended for individuals younger than 40 years whose LDL level is greater than 200 mg/mL and for individuals older than 40 years whose LDL level is greater than 250 mg/mL. DNA analysis for mutations in the genes that cause FH is readily available.

▶ Treatment

Statins, usually at high doses, can reduce LDL levels, occasionally to acceptable levels. The earlier in life that treatment is begun, the better the outcome of reducing mortality from atherosclerosis. In homozygous FH, if high-dose statins do not reduce LDL sufficiently, then plasmapheresis to reduce LDL is often needed. If these measures are not effective enough, treatment with an antibody that inhibits the product of the *PCSK9* gene can be a quite expensive adjunct to standard therapy.

At-risk relatives should be screened for FH by measuring LDL levels; identifying the mutation in the family and utilizing that for screening is being increasingly done.

▶ When to Refer

- For genetic counseling of the patient, his or her parents, siblings, and offspring.

▶ When to Admit

- For signs or symptoms of acute arterial occlusive events.

FRAGILE X MENTAL RETARDATION

ESSENTIALS OF DIAGNOSIS

- ▶ Expanded trinucleotide repeat (more than 200) in the *FMR1* gene.
- ▶ **Males:** mental retardation and autism; large testes after puberty.
- ▶ **Females:** learning disabilities or mental retardation; premature ovarian failure.
- ▶ Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat (55–200) expansion (premutation carriers).

▶ Clinical Findings

A. Symptoms and Signs

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 4000 males is affected. The central nervous system phenotype includes autism spectrum, impulsivity and aggressiveness, and repetitive behaviors. The condition also affects intellectual function in females, although less severely and about 50% less frequently than in males. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties, anxiety, sensory issues, or frank retardation. Affected males show macro-orchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive abnormalities. Male and female premutation carriers are at risk for mood and anxiety disorders and the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter may be evident on MRI before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population (1/130–1/600), older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

B. Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

▶ Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation. Newborn screening based on hypermethylation of the *FMR1* gene is being considered as a means of early detection and intervention.

▶ Treatment

Several treatments that address the imbalances in neurotransmission have been developed based on the mouse model and are in clinical trials. Valproic acid may reduce

symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

► When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

Hagerman RJ et al. Fragile X syndrome. *Nat Rev Dis Primers*. 2017 Sep 29;3:17065. [PMID: 28960184]

GAUCHER DISEASE

ESSENTIALS OF DIAGNOSIS

- Deficiency of beta-glucocerebrosidase.
- Anemia and thrombocytopenia.
- Enlargement of the liver and spleen.
- Pathologic fractures.

► Clinical Findings

A. Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of beta-glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. The abdomen can become painfully distended from enlargement of the liver and spleen. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed “crises”) are reminiscent of those in sickle cell disease. A hip fracture in a patient of any age with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease. Peripheral neuropathy may develop in patients.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

B. Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Hundreds of mutations have been found to

cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

► Prevention

Gaucher disease is the most common lysosomal storage disorder. Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible. Because of an increased risk of malignancy, especially plasma cell myeloma and other hematologic cancers, regular screening of adults with Gaucher disease is warranted.

► Treatment

A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis reduces total body stores of glycolipid and improves orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed \$300,000 per year for a severely affected adult patient. Eliglustat tartrate is an oral inhibitor of glucosylceramide synthase and reduces the compound that accumulates; while still quite expensive, this approach eliminates the need for frequent intravenous infusions. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. In adults with thrombocytopenia due to splenic sequestration, enzyme replacement often obviates the need for splenectomy.

DISORDERS OF HOMOCYSTEINE METABOLISM

ESSENTIALS OF DIAGNOSIS

- Hyperhomocysteinemia: more vascular disease but lowering homocysteine levels is not helpful.
- Homocystinuria: Marfan-like habitus, ectopia lentis, mental retardation, thromboses.
- Elevated homocysteine in the urine or plasma.

General Considerations

Patients with clinical and angiographic evidence of coronary artery disease and cerebrovascular and peripheral vascular diseases tend to have higher levels of plasma homocysteine than persons without these vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine beta-synthase deficiency (see below), there is little supporting evidence. Rather, an important factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B₆) and vitamin B₁₂ are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copy of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B₆ and B₁₂. In the United States, cereal grains are fortified with folic acid. However, therapy with B vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for cardiovascular disease has received modest direct support in clinical trials. Hyperhomocysteinemia occurs with end-stage chronic kidney disease. In the general population, elevated homocysteine correlates with cognitive impairment.

Clinical Findings

A. Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine beta-synthase deficiency and exhibits autosomal recessive inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Thus, the diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors. Bone mineral density is reduced in untreated patients. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. In addition, homozygotes for a common mutant allele, p.I278T, show marked clinical variability, with some unaffected as adults.

B. Laboratory Findings

Although many mutations have been identified in the cystathionine beta-synthase gene (*CBS*), amino acid analysis of

plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

Prevention

About 50% of patients have a form of cystathionine beta-synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine (50–500 mg/day) and folate (5–10 mg/day). For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine nonresponders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

KLINEFELTER SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Males with hypergonadotropic hypogonadism and small testes.
- ▶ 47,XXY karyotype.

Clinical Findings

A. Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, sparse body hair, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The incidence is 1 in 660 newborn males, but the

diagnosis is often not made until a man is evaluated for inability to conceive. Intellectual disability is somewhat more common than in the general population. Many men with Klinefelter syndrome have language-based learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of osteoporosis, breast cancer, and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

B. Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY, but other sex chromosome anomalies cause variations of Klinefelter syndrome.

► Prevention

Screening for cancer (especially of the breast), deep venous thrombosis, and glucose intolerance are indicated.

► Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. But men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore genomic analysis of a blastocyst should be considered before implantation.

MARFAN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- ▶ Ectopia lentis and myopia.
- ▶ Aortic root dilation and dissection; mitral valve prolapse.
- ▶ Mutation in *FBN1*, the gene encoding fibrillin-1.

► General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural

ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often with elongated chordae tendineae, which on occasion may rupture.

► Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine beta-synthase deficiency also have dislocated lenses, tall, disproportionate stature, and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

B. Laboratory Findings

Mutations in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the *FBN1* mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF)-beta activity. Mutations in either of two receptors for TGF-beta (*TGFBR1* and *TGFBR2*) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance. Mutations in more than one dozen other genes can predispose adults to thoracic aortic aneurysm and dissection.

► Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in *FBN1* has been found.

► Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for

diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic root diameter and mitral valve function. Long-term beta-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily) retards the rate of aortic dilation. While inhibition of the TGF-beta signaling pathway through angiotensin receptor blockade (ARB) in mice with Marfan syndrome is highly effective, ARB treatment in humans is no more effective than beta-adrenergic blockade. Calcium channel blockers, once used as a substitute for beta-blockade, are detrimental to the aorta. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: less than 40 mm) prolongs life. A procedure to resuspend the patient's native aortic valve and replace just the aneurysmal sinuses of Valsalva and ascending aorta avoids the need for lifelong anticoagulation. Women with Marfan syndrome are at heightened risk for aortic dissection in the peripartum and postpartum periods. Having an aortic root dimension greater than 40 mm should prompt consideration for prophylactic, valve-sparing aortic repair before undertaking a pregnancy.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or heart failure secondary to aortic or mitral regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic and mitral valve surgery, life expectancy has increased by several decades.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent epistaxis.
- ▶ Mucocutaneous telangiectases.
- ▶ Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

A. Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed “Osler-Weber-Rendu syndrome,” is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

B. Laboratory Findings

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified, and molecular analysis to identify them is available; these mutations in *ENG*, *ALK1*, and *SMAD4* account for about 87% of families with HHT. When the familial mutation is known, molecular testing is far more cost effective than repeated clinical screening of relatives who are at risk.

Prevention

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain

Bradley TJ et al. The expanding clinical spectrum of extracardiovascular and cardiovascular manifestations of heritable thoracic aortic aneurysm and dissection. *Can J Cardiol.* 2016 Jan;32(1):86–99. [PMID: 26724513]

Pyeritz RE. Etiology and pathogenesis of the Marfan syndrome: current understanding. *Ann Cardiothorac Surg.* 2017 Nov;6(6):595–8. [PMID: 29270371]

abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis (see Table 33–5). All intravenous lines (except those for transfusion of red blood cells and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

► Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when “bubbles” appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1–2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 6 months and 3 years. A person with a negative contrast echocardiogram should have the test repeated

every 5 years. Several studies suggest that treatment with anti-estrogenic agents (eg, tamoxifen), thalidomide or its relatives, or anti-vascular endothelial growth factor agents (eg, bevacizumab) can reduce epistaxis and gastrointestinal bleeding and improve hepatic shunting. However, two randomized, controlled clinical trials of intranasal bevacizumab therapy failed to show an improvement in epistaxis.

Sports Medicine & Outpatient Orthopedics

Anthony Luke, MD, MPH
C. Benjamin Ma, MD

Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as traumatic (ie, injury-related) or atraumatic (ie, degenerative or overuse syndromes) as well as acute or chronic. The history and physical examination are sufficient in most cases to establish the working diagnosis; the mechanism of injury is usually the most helpful part of the history in determining the diagnosis.

SHOULDER

1. Subacromial Impingement Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Shoulder pain with overhead motion.
- ▶ Night pain with sleeping on shoulder.
- ▶ Numbness and pain radiation below the elbow are usually due to cervical spine disease.

▶ General Considerations

The shoulder is a ball and socket joint. The socket is very shallow, however, which enables this joint to have the most motion of any joint. The shoulder, therefore, relies heavily on the surrounding muscles and ligaments to provide stability. The subacromial impingement syndrome describes a collection of diagnoses that cause mechanical inflammation in the subacromial space. Causes of impingement syndrome can be related to muscle strength imbalances, poor scapula control, rotator cuff tears, subacromial bursitis, and bone spurs.

With any shoulder problem, it is important to establish the patient's hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint. For example, baseball pitchers with impingement syndrome may complain of pain while throwing. Alternatively, older adults with even full-thickness rotator cuff tears may not complain of any pain because the demands on the joint are low.

▶ Clinical Findings

A. Symptoms and Signs

Subacromial impingement syndrome classically presents with one or more of the following: pain with overhead activities, nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). On inspection, there may be appreciable atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or “dyskinesia.” The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, the patient can have tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion (Table 41–1) but should have preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 41–1).

B. Imaging

The following four radiographic views should be ordered to evaluate subacromial impingement syndrome: the anteroposterior (AP) scapula, the AP acromioclavicular joint, the lateral scapula (scapular Y), and the axillary lateral. The AP scapula view can rule out glenohumeral joint arthritis. The AP acromioclavicular view evaluates the acromioclavicular joint for inferior spurs. The scapula Y view evaluates the acromial shape, and the axillary lateral view visualizes the glenohumeral joint as well and for the presence of os acromiale.

MRI of the shoulder may demonstrate full- or partial-thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized on ultrasound, although it is more difficult to identify partial tears from small full thickness than on MRI.

▶ Treatment

A. Conservative

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity modification, and physical therapy exercises. Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle

Table 41–1. Shoulder examination.

Maneuver	Description
Inspection	Check the patient's posture and "SEADS" (swelling, erythema, atrophy, deformity, surgical scars).
Palpation	Include important landmarks: acromioclavicular (AC) joint, long head of biceps tendon, coracoid, and greater tuberosity (supraspinatus insertion).
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs).
Flexion	Move the arm forward as high as possible in the sagittal plane.
External rotation	Check with the patient's elbow touching their body so that external rotation occurs predominantly at the glenohumeral joint.

(continued)

Table 41–1. Shoulder examination. (continued)

Maneuver	Description
Internal rotation 	The patient is asked to reach the thumbs as high as possible behind the spine on each side. The clinician can record the highest spinous process that the individual can reach on each side (iliac crest = L4, inferior angle of scapula = T8).
Rotator Cuff Strength Testing Supraspinatus (open can) test 	Perform resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees to test for supraspinatus tendon strength ("open can" test), or with shoulder abduction at 30 degrees and flexion to 30 degrees ("empty can" test).
External rotation 	The patient resists by externally rotating the arms with elbows at his or her side.

(continued)

Table 41-1. Shoulder examination. (continued)

Maneuver	Description
Internal rotation (lift-off test) 	A positive “lift-off” test is the inability of the patient to hold his or her hand away from the body when reaching toward the small of the back. The clinician pushes the patient’s hand toward the back while the patient resists. A positive lift-off indicates subscapularis tendon insufficiency.
Internal rotation (belly-press test) 	A positive “belly-press” test is the inability to hold the elbow in front of the trunk while pressing down with the hand on the belly. A positive belly press test indicates subscapularis tendon insufficiency.
Impingement Testing	
Neer impingement sign 	Perform by having the clinician flex the shoulder maximally in an overhead position. The test is positive when pain is reproduced with full passive shoulder flexion. Sensitivity is 79%; specificity is 53%.

(continued)

Table 41–1. Shoulder examination. (continued)

Maneuver	Description
Hawkins impingement sign 	Perform with the shoulder forward flexed 90 degrees and the elbow flexed at 90 degrees. The shoulder is then maximally internally rotated to impinge the greater tuberosity on the undersurface of the acromion. The test is considered positive when the patient's pain is reproduced by this maneuver. Sensitivity is 79%; specificity is 59%.

strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, which may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong evidence supporting the effectiveness of ice and NSAIDs as a prolonged therapy. In a Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears.

► When to Refer

- Failure of conservative treatment over 3 months.
- Young and active patients with impingement due to full-thickness rotator cuff tears.

Hermans J et al. Does this patient with shoulder pain have rotator cuff disease? The Rational Clinical Examination systematic review. *JAMA*. 2013 Aug 28;310(8):837–47. [PMID: 23982370]

2. Rotator Cuff Tears

ESSENTIALS OF DIAGNOSIS

- ▶ A common cause of shoulder impingement syndrome after age 40.
- ▶ Difficulty lifting the arm with limited active range of motion.
- ▶ Weakness with resisted strength testing suggests full-thickness tears.
- ▶ Tears can occur following trauma or can be more degenerative.

► General Considerations

Rotator cuff tears can be caused by acute injuries related to falls on an outstretched arm or to pulling on the shoulder. It can also be related to chronic repetitive injuries with overhead movement and lifting. Partial rotator cuff tears are one of the most common reasons for impingement syndrome. Full-thickness rotator cuff tears are usually more symptomatic and may require surgical treatment. The most commonly torn tendon is the supraspinatus.

► Clinical Findings

A. Symptoms and Signs

Most patients complain of weakness or pain with overhead movement. Night pain is also a common complaint. The clinical findings with rotator cuff tears include those of the impingement syndrome except that with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Supraspinatus tendon strength is tested with resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees (“open can” test). Infraspinatus/teres minor strength is tested with resisted shoulder external rotation with shoulder at 0 degrees abduction, elbow by side. Subscapularis strength is tested with the “lift-off” or “belly-press” tests. The affected patient usually also has positive Neer and Hawkins impingement tests (Table 41–1).

B. Imaging

Recommended radiographs are similar to impingement syndrome: AP scapula (glenohumeral), axillary lateral, supraspinatus outlet, and AP acromioclavicular joint views. The AP scapula view is useful in visualizing rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder. Axillary lateral views show superior elevation of the humeral head in relation to the center of the glenoid. Supraspinatus outlet views allow evaluation of the shape of the acromion.

High-grade acromial spurs are associated with a higher incidence of rotator cuff tears. The AP acromioclavicular joint view evaluates for the presence of acromioclavicular joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff injuries.

MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (less than 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

► Treatment

Partial rotator cuff tears may heal with scarring. Most partial rotator cuff tears can be treated with physical therapy and scapular and rotator cuff muscle strengthening. However, research suggests that 40% of the partial-thickness tears progress to full-thickness tears in 2 years. Physical therapy can strengthen the remaining muscles to compensate for loss of strength and can have high rate of success for chronic tears. Physical therapy is also an option for older sedentary patients. On the contrary, **full-thickness rotator cuff tears** do not heal well and also have a tendency to increase in size with time. Forty-nine percent of the full-thickness tears get bigger on an average of 2.8 years. When tears get larger, they are also associated with worsening pain. Fatty infiltration is a degenerative process where muscle is being replaced by fat following injury to the rotator cuff tendons. Fatty infiltration progresses in full-thickness rotator cuff tears and it is a negative prognostic factor for successful surgical treatment. Fatty infiltration is an irreversible process so operative interventions are usually performed when the degree of infiltration is low. **Most young active patients with acute, full-thickness tears should be treated with operative fixation.** Full-thickness subscapularis tendon tears should undergo surgical repair as untreated tears usually lead to premature osteoarthritis (OA) of the shoulder. Nonetheless, physical therapy is indicated for atraumatic degenerative rotator cuff tears and success can be as high as 70%.

► When to Refer

- Young and active patients with full-thickness rotator cuff tears.
- Partial tears with greater than 50% involvement and with significant pain.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full-thickness subscapularis tears.

3. Shoulder Dislocation & Instability

ESSENTIALS OF DIAGNOSIS

- Most dislocations (95%) are in the anterior direction.
- Pain and apprehension with an unstable shoulder that is abducted and externally rotated.
- Acute shoulder dislocations should be reduced as quickly as possible, using manual relocation techniques if necessary.

► General Considerations

The shoulder is a ball and socket joint, similar to the hip. However, the bony contours of the shoulder bones are much different than the hip. Overall, the joint has much less stability than the hip, allowing greater movement and action. Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. If patients have poor scapular control or weak rotator cuff tendons or tears, their shoulders are more likely to have instability. Ninety-five percent of the shoulder dislocations/instability occur in the anterior direction. Dislocations usually are caused by a fall on an outstretched and abducted arm. Patients complain of pain and feeling of instability when the arm is in the abducted and externally rotated position. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to instability. The rate of repeated dislocation is directly related to the patient's age: patients aged 21 years or younger have a 70–90% risk of redislocation, whereas patients aged 40 years or older have a much lower rate (20–30%). Other risks include male gender and patients with hyperlaxity. Ninety percent of young active individuals who had traumatic shoulder dislocation have labral injuries often described as Bankart lesions when the anterior inferior labrum is torn, which can lead to continued instability. Older patients (over age 55 years) are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in swimmers, gymnasts, and pitchers as well as other athletes involved in overhead and throwing sports.

► Clinical Findings

A. Symptoms and Signs

For acute traumatic dislocations, patients usually have an obvious deformity with the humeral head dislocated anteriorly. The patient holds the shoulder and arm in an externally rotated position. The patient complains of acute pain and deformity that are improved with manual relocation of the shoulder. Reductions are usually performed in the emergency department. Even after reduction, the patient will continue to have limited range of motion and pain for 4–6 weeks, especially following a first-time shoulder dislocation.

Patients with recurrent dislocations can have less pain with subsequent dislocations. Posterior dislocations can be easily missed because the patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. Patients complain of difficulty pushing open a door.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually complain of a “sliding” sensation during exercises or strenuous activities such as throwing. Such dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test, the load and shift test, and the O’Brien test (Table 41–1). Most patients with persistent shoulder instability have preserved range of motion.

B. Imaging

Radiographs for acute dislocations should include a standard trauma series of AP and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed easily with one AP view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a patient with a painful shoulder dislocation. A scapula Y view in the acute setting is insufficient to diagnose dislocation. For chronic injuries or symptomatic instability, these recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indented compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation). MRI is commonly used to show soft tissue injuries to the labrum and to visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures. Three-dimensional CT scans are being used to determine the significance of bone loss.

Treatment

For **acute dislocations**, the shoulder should be reduced as soon as possible. The Stimson procedure is the least traumatic method and is quite effective. The patient lies prone with the dislocated arm hanging off the examination table with a weight applied to the wrist to provide traction for 20–30 minutes. Afterward, gentle medial mobilization can be applied manually to assist the reduction. The shoulder can also be reduced with axial “traction” on the arm with “counter-traction” along the trunk. The patient should be sedated and relaxed. The shoulder can then be gently internally and externally rotated to guide it back into the socket.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. For patients with a traumatic incident and unilateral shoulder dislocation, a Bankart lesion is commonly present. The risk of recurrence is dependent on

the age of first shoulder dislocation. Young patients (less than 27 years of age) can have recurrence up to 70% whereas patients older than 40 years old have recurrences as low as 10%. However, once the patient has a second dislocation, the recurrence rate is extremely high, up to 95%, regardless of age. Operative intervention is the only treatment that has been shown to decrease recurrence. Open and arthroscopic stabilization can have very similar outcomes. Repeat dislocation has been shown to increase the risk of arthritis and further bony deterioration.

The treatment of **atraumatic shoulder instability** is different than traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. Surgical reconstructions are less successful for atraumatic shoulder instability than for traumatic shoulder instability.

When to Refer

- Patients who are at risk for second dislocation, such as young patients, certain job holders (eg, police officers, firefighters, and rock climbers) to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to conservative approach or who have chronic instability.

Chalmers PN et al. Do arthroscopic and open stabilization techniques restore equivalent stability to the shoulder in the setting of anterior glenohumeral instability? A systematic review of overlapping meta-analysis. *Arthroscopy*. 2015 Feb; 31(2):355–63. [PMID: 25217207]

Olds M et al. Risk factors which predispose first-time traumatic anterior shoulder dislocations to recurrent instability in adults: a systematic review and meta-analysis. *Br J Sports Med*. 2015 Jul;49(14):913–22. [PMID: 25900943]

4. Adhesive Capsulitis (“Frozen Shoulder”)

ESSENTIALS OF DIAGNOSIS

- ▶ Very painful shoulder triggered by minimal or no trauma.
- ▶ Pain out of proportion to clinical findings during the inflammatory phase.
- ▶ Stiffness during the “freezing” phase and resolution during the “thawing” phase.

General Considerations

Adhesive capsulitis (“frozen shoulder”) is seen commonly in patients 40 to 65 years old. It is more commonly seen in women than men, especially in perimenopausal women or in patients with endocrine disorders, such as diabetes mellitus or thyroid disease. There is higher incidence following breast cancer care (such as mastectomy). Adhesive capsulitis is a self-limiting but very debilitating disease.

Clinical Findings

A. Symptoms and Signs

Patients usually present with a painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk (Table 41-1). Strength is usually normal but it can appear diminished when the patient is in pain.

There are three phases: the inflammatory phase, the freezing phase, and the thawing phase. During the inflammatory phase, which usually lasts 4–6 months, patients complain of a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the “freezing” phase, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The “thawing” phase can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

B. Imaging

Standard AP, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. Imaging can also rule out calcific tendinitis, which is an acute inflammatory process in which calcifications are visible in the soft tissue. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic workup.

Treatment

Adhesive capsulitis is caused by acute inflammation of the capsule followed by scarring and remodeling. During the acute “freezing” phase, NSAIDs and physical therapy are recommended to maintain motion. There is also evidence of short-term benefit from intra-articular corticosteroid injection or oral prednisone. A randomized control trial showed that intra-articular corticosteroid injection provided better pain relief than NSAIDs in the first 8 weeks. However, no difference was seen in range of motion or pain after 12 weeks, which is similar to other noncontrolled studies. One study demonstrated improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the “freezing” phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the “thawing” phase as it is during the “freezing” phase, and the shoulder symptoms usually resolve with time. Surgical treatments, which are rarely indicated, include manipulation under anesthesia and arthroscopic release.

When to Refer

- When the patient does not respond after more than 6 months of conservative treatment.
- When there is no progress or worsening range of motion over 3 months.

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- ▶ Alarming symptoms include unexplained weight loss, failure to improve with treatment, severe pain for more than 6 weeks, night or rest pain.
- ▶ Cauda equina syndrome is an emergency; often presents with bowel or bladder symptoms (or both).

General Considerations

Low back pain remains the most common cause of disability for patients under the age of 45 and is the second most common cause for primary care visits. The annual prevalence of low back pain is 15–45%. Low back and neck pain is estimated to be the third-largest condition of health care spending at \$87.6 billion. Low back pain is the condition associated with the highest years lived with disability. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. The exact cause of the low back pain is often difficult to diagnose; its cause is often multifactorial, although there are usually degenerative changes in the lumbar spine.

Alarming symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for more than 6 weeks, and pain at night or rest. History of cancer and age older than 50 years are other risk factors for malignancy. Alarming symptoms for infection include fever, rest pain, recent infection (urinary tract infection, cellulitis, pneumonia), or history of immunocompromise or injection drug use. The **cauda equina syndrome** is suggested by urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits. Risk factors for back pain due to vertebral fracture include use of corticosteroids, age over 70 years, history of osteoporosis, severe trauma, and presence of a contusion or abrasion. Back pain may also be the presenting symptom in other serious medical problems, including abdominal aortic aneurysm, peptic ulcer disease, kidney stones, or pancreatitis.

Clinical Findings

A. Symptoms and Signs

The physical examination can be conducted with the patient in the standing, sitting, supine, and finally prone positions to avoid frequent repositioning of the patient. In the standing position, the patient's posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed while standing. The common directions include flexion, extension, rotation, and lateral bending. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis.

With the patient sitting, motor strength, reflexes, and sensation can be tested (Table 41–2). The major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for about 5 seconds. Comparing the strength bilaterally to detect subtle muscle weakness is important. Similarly, sensory testing to light touch can be checked in specific dermatomes for corresponding nerve root function. Knee (femoral nerve L2–4), ankle (deep peroneal nerve L4–L5), and Babinski (sciatic nerve L5–S1) reflexes can be checked with the patient sitting.

In the supine position, the hip should be evaluated for range of motion, particularly internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots.

Finally, in the prone position, the clinician can carefully palpate each vertebral level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda

equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering.

B. Imaging

In the absence of alarming “red flag” symptoms suggesting infection, malignancy, or cauda equina syndrome, most patients do not need diagnostic imaging, including radiographs, in the first 6 weeks. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 41–3. Most clinicians obtain radiographs for new back pain in patients older than 50 years. If done, radiographs of the lumbar spine should include AP and lateral views. Oblique views can be useful if the neuroforamina or bone lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms not responding to conservative treatment or in the presence of red flags of serious conditions.

C. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

Treatment

A. Conservative

Nonpharmacologic treatments are key in the management of low back pain. Education alone improves patient

Table 41–2. Neurologic testing of lumbosacral nerve disorders.

Nerve Root	Motor	Reflex	Sensory Area
L1	Hip flexion	None	Groin
L2	Hip flexion	None	Thigh
L3	Extension of knee	Knee jerk	Knee
L4	Dorsiflexion of ankle	Knee jerk	Medial calf
L5	Dorsiflexion of first toe	Babinski reflex	First dorsal web space between first and second toes
S1	Plantar flexion of foot, knee flexors, or hamstrings	Ankle jerk	Lateral foot
S2	Knee flexors or hamstrings	Knee flexor	Back of the thigh
S2–S4	External anal sphincter	Anal reflex, rectal tone	Perianal area

Table 41–3. AHRQ criteria for lumbar radiographs in patients with acute low back pain.

Possible fracture Major trauma Minor trauma in patients > 50 years Long-term corticosteroid use Osteoporosis > 70 years
Possible tumor or infection > 50 years < 20 years History of cancer Constitutional symptoms Recent bacterial infection Injection drug use Immunosuppression Supine pain Nocturnal pain

AHRQ, Agency for Healthcare Research and Quality. Reproduced, with permission, from Suarez-Almazor ME et al. Use of lumbar radiographs for the early diagnosis of low back pain. Proposed guidelines would increase utilization. JAMA. 1997 Jun;277:1782–6. Copyright © 1997 American Medical Association. All rights reserved.

satisfaction with recovery and recurrence. Patients require information and reassurance, especially when diagnostic procedures are not necessary. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening, weight loss, and smoking cessation. Tai chi, mindfulness-based stress reduction, and yoga have shown benefit for chronic low back pain patients. The effectiveness of exercise, psychological therapies, and multidisciplinary rehabilitation, have been shown to be modestly effective for acute low back pain (strength of evidence, low).

Physical therapy exercise programs can be tailored to the patient's symptoms and pathology. A randomized controlled trial demonstrated that individualized physical therapy was clinically more beneficial than advice alone with sustained improvements at 6 months and 12 months. Strengthening and stabilization exercises effectively reduce pain and functional limitation compared with usual care. Heat and cold treatments have not shown any long-term benefits but may be used for symptomatic treatment. The efficacy of transcutaneous electrical nerve stimulation (TENS), back braces, and physical agents are unproven. Spinal manipulation, massage, and acupuncture does have limited, low evidence for chronic low back pain. Improvements in posture including chair ergonomics or standing desks, core stability strengthening, physical conditioning, and modifications of activities to decrease physical strain are keys for ongoing management. Radiofrequency denervation of facet joints, sacroiliac joints, or intervertebral disks, did not result in clinically important improvement in chronic low back even when combined with a standardized exercise program in randomized controlled trials.

NSAIDs are effective in the early treatment of low back pain (see Chapter 20). Acetaminophen and oral corticosteroids are relatively ineffective for chronic low back. There is limited evidence that muscle relaxants provide short-term relief; since these medications have addictive potential, they should be used with care. Muscle relaxants are best used if there is true muscle spasm that is painful rather than simply a protective response. Opioids alleviate pain in the short term, but have the usual side effects and concerns of long-term opioid use (see Chapter 5). Treatment of more chronic neuropathic pain with alpha-2-delta ligands (eg, gabapentin), serotonin-norepinephrine reuptake inhibitors (eg, duloxetine), or tricyclic antidepressants (eg, nortriptyline) may be helpful. Epidural injections may reduce pain in the short term, and appear to reduce the need for surgery in some patients within a 1-year period but not longer.

B. Surgical

Surgical indications for back surgery include cauda equina syndrome, ongoing morbidity with no response to more than 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important and the specific surgery recommended should have very clear indications. Patients should

understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is relatively asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; deep venous thrombosis; and death.

► When to Refer

- Patients with the cauda equina syndrome.
- Patients with cancer, infection, fracture, or severe spinal deformity.
- Patients who have not responded to conservative treatment.

2. Spinal Stenosis

ESSENTIALS OF DIAGNOSIS

- Pain is usually worse with back extension and relieved by sitting.
- Occurs in older patients.
- May present with neurogenic claudication symptoms with walking.

► General Considerations

OA in the lumbar spine can cause narrowing of the spinal canal. A large disk herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in “claudication” symptoms with ambulation. The condition usually affects patients aged 50 years or older.

► Clinical Findings

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting (“neurogenic claudication”). On examination,

patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating down the legs. A thorough neurovascular examination is recommended (Table 41–2).

► Treatment

Exercises, usually flexion-based as demonstrated by a physical therapist, can help relieve symptoms. Physical therapy showed similar results as surgical decompression in a randomized trial, though there was a 57% crossover rate from physical therapy to surgery. Facet joint corticosteroid injections can also reduce pain symptoms. A 2014 randomized trial found a benefit overall from epidural injection at 6 weeks, but did not find a difference when patients received injections of corticosteroids plus lidocaine compared to lidocaine alone. The extended benefit of epidural lidocaine injection alone is not well studied, so present practice most likely will continue to include corticosteroids. Epidural corticosteroid injections similarly showed only modest but significant improvement compared to gabapentin in patients with worse leg symptoms.

Surgical treatments for spinal stenosis include spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebra to eliminate motion and diminish pain from the arthritic joints). In one multicenter randomized trial, subgroups initially improved significantly more with surgery than with nonoperative treatment. Variables associated with greater treatment effects included lower baseline disability scores, not smoking, neuroforaminal stenosis, predominant leg pain rather than back pain, not lifting at work, and the presence of a neurologic deficit. However, long-term follow-up of the patients with symptomatic spinal stenosis who received surgery in the multicenter randomized trial showed less benefit of surgery between 4 and 8 years, suggesting that the advantage of surgery for spinal stenosis diminishes over time. A Cochrane review of 24 randomized controlled trials of treatments for lumbar spinal stenosis showed that various surgeries including decompression plus fusion and interspinous process spacers were not superior to conventional spinal decompression surgery alone.

► When to Refer

- If a patient exhibits radicular or claudication symptoms for longer than 12 weeks.
- MRI or CT confirmation of significant, symptomatic spinal stenosis.

Cohen SP et al. Epidural steroid injections compared with gabapentin for lumbosacral radicular pain: multicenter randomized double blind comparative efficacy study. *BMJ*. 2015 Apr 16;350:h1748. [PMID: 25883095]

Machado GC et al. Surgical options for lumbar spinal stenosis. *Cochrane Database Syst Rev*. 2016 Nov 1;11:CD012421. [PMID: 27801521]

3. Lumbar Disk Herniation

ESSENTIALS OF DIAGNOSIS

- Pain with back flexion or prolonged sitting.
- Radicular pain into the leg due to compression of neural structures.
- Lower extremity numbness and weakness.

► General Considerations

Lumbar disk herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disk contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disk herniations usually occur from degenerative disk disease (dessication of the annulus fibrosis) in patients between 30 and 50 years old. The L5–S1 disk is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency.

► Clinical Findings

A. Symptoms and Signs

Discogenic pain typically is localized in the low back at the level of the affected disk and is worse with activity. “Sciatica” causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disk herniation can cause numbness and weakness, including weakness with plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient complains of perianal numbness or bowel or bladder incontinence.

B. Imaging

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disk space narrowing, and OA changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned.

► Treatment

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs and other analgesics; and physical therapy, including core stabilization and McKenzie exercises. Following nonsurgical treatment for a lumbar disk for over 1 year, the incidence of low back pain recurrence is at least 40% and is predicted by

longer time to initial resolution of pain. In a randomized trial, oral prednisone caused a modest improvement in function at 3 weeks, but there was no significant improvement in pain in patients with acute radiculopathy who were monitored for 1 year. The initial dose for oral prednisone is approximately 1 mg/kg once daily with tapering doses over 10–15 days. Analgesics for neuropathic pain, such as the calcium channel α -2-delta ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (see Chapter 5). Epidural and transforaminal corticosteroid injections can be beneficial. A systematic review demonstrated strong evidence that fluoroscopic-guided epidural injections gave short-term benefit (less than 6 months) in acute radicular pain for individuals. However, epidural injections have not shown any change in long-term surgery rates for disk herniations.

The severity of pain and disability as well as failure of conservative therapy were the most important reasons for surgery. A large trial has shown that patients who underwent surgery for a lumbar disk herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return to work status after 4-year follow-up. Patients with sequestered fragments, symptom duration greater than 6 months, higher levels of low back pain, or who were neither working nor disabled at baseline showed greater surgical treatment effects. Microdiscectomy is the standard method of treatment with a low rate of complications and satisfactory results over 90% in the largest series. Minimally invasive techniques include percutaneous endoscopic discectomy, which involves using an endoscope to remove fragments of disk herniation fragments (interlaminar or transforaminal approaches) under local anesthesia, although results are less successful than microdiscectomy. Disk replacement surgery has shown benefits in short-term pain relief, disability, and quality of life compared with spine fusion surgery.

When to Refer

- Cauda equina syndrome.
- Progressive worsening of neurologic symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

4. Neck Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic neck pain is mostly caused by degenerative joint disease; whiplash often follows a traumatic neck injury.
- ▶ Poor posture is often a factor for persistent neck pain.

General Considerations

Most neck pain, especially in older patients, is due to mechanical degeneration involving the cervical disks, facet joints, and ligamentous structures and may occur in the setting of degenerative changes at other sites. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. **Posture is a very important factor, especially in younger patients.** Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. Whiplash occurs from rapid flexion and extension of the neck and affects 15–40% of people in motor vehicle accidents; chronic pain develops in 5–7%. Neck fractures are serious traumatic injuries acutely and can lead to OA in the long term. Ultimately, many degenerative conditions of the neck result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures.

Cervical radiculopathy can cause neurologic symptoms in the upper extremities usually involving the C5–C7 disks. Patients with neck pain may report associated headaches and shoulder pain. Both peripheral nerve entrapment and cervical radiculopathy, known as a “double crush” injury, may develop. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain. Other causes of neck pain include rheumatoid arthritis, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and Parsonage-Turner syndrome can mimic myelopathy from cervical arthritis.

Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity.

The patient's posture should be assessed, checking for shoulder rolled forward or head forward posture as well as

scoliosis in the thoracolumbar spine. Patients with discogenic neck pain often complain of pain with flexion, which causes cervical disks to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. Limitation of cervical movements is the most common objective finding.

A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C6], opponens strength (thumb to pinky) [C7], and finger abductors and adductors strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The Spurling test involves asking the patient to rotate and extend the neck to one side (Table 41–4). The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed.

B. Imaging and Special Tests

Radiographs of the cervical spine include the AP and lateral view of the cervical spine. The odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can

provide further information about arthritis changes and assess the neural foramina for narrowing. Plain radiographs can be completely normal in patients who have suffered an acute cervical strain. Comparative reduction in height of the involved disk space and osteophytes are frequent findings when there are degenerative changes in the cervical spine. Loss of cervical lordosis is commonly seen but is nonspecific.

MRI is the best method to assess the cervical spine since the soft tissue structures (such as the disks, spinal cord, and nerve roots) can be evaluated. If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently. CT scanning is the most useful method if bony abnormalities, such as fractures, are suspected.

EMG is useful in order to differentiate peripheral nerve entrapment syndromes from cervical radiculopathy.

Treatment

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. More frequent observation of individuals in whom very severe symptoms are present early on after an injury is recommended because high pain-related disability is a predictor of poor outcome at 1 year even if individuals decline care. Ergonomics should be assessed at work and home. A course of neck stretching, strengthening and postural exercises in physical therapy have demonstrated benefit in relieving symptoms. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10/million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. NSAIDs are commonly used and opioids may be needed in cases of severe neck pain. Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course of oral prednisone (5–10 days) can be considered (starting at 1 mg/kg). Cervical foraminal or facet joint injections can also reduce symptoms. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases, but are still considered as treatments of last resort. Cervical disk arthroplasty (replacement) has become more common as a treatment option. A meta-analysis of 18 randomized controlled trials showed that cervical disk arthroplasty was superior to anterior discectomy and fusion for the treatment of symptomatic cervical disk disease, with better success and less reoperation rates.

When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

Table 41–4. Spine: neck examination.

Maneuver	Description
Inspection	Check the patient's posture in the standing position. Assess for cervical hyperlordosis, head forward posture, kyphosis, scoliosis, torticollis.
Palpation	Include important landmarks: spinous process, facet joints, paracervical muscles (sternocleidomastoid, scalene muscles).
Range of motion testing	Check range of motion in the cervical spine, especially with flexion and extension. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions. Pain and radicular symptoms can be exacerbated by range of motion testing.
Neurologic examination	Check motor strength, reflexes and dermatomal sensation in the upper (and lower if necessary) extremities.
Spurling test	Involves asking the patient to rotate and extend the neck to one side. The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression.

UPPER EXTREMITY

1. Lateral & Medial Epicondylitis

ESSENTIALS OF DIAGNOSIS

- ▶ Tenderness over the lateral or medial epicondyle.
- ▶ Diagnosis of tendinopathy is confirmed by pain with resisted strength testing and passive stretching of the affected tendon and muscle unit.
- ▶ Physical therapy and activity modification are more successful than anti-inflammatory treatments.

General Considerations

Tendinopathy involving the wrist extensors, flexors, and pronators are very common complaints. The underlying mechanism is chronic repetitive overuse causing micro-trauma at the tendon insertion, although acute injuries can occur as well if the tendon is strained due to excessive loading. The traditional term “epicondylitis” is a misnomer because histologically tendinosis or degeneration in the tendon is seen rather than acute inflammation. Therefore, these entities should be referred to as “tendinopathy” or “tendinosis.” Lateral epicondylitis involves the wrist extensors, especially the extensor carpi radialis brevis. This is usually caused by lifting with the wrist and the elbow extended. Medial epicondylitis involves the wrist flexors and most commonly the pronator teres tendon. Ulnar neuropathy and cervical radiculopathy should be considered in the differential diagnosis.

Clinical Findings

A. Symptoms and Signs

For lateral epicondylitis, the patient describes pain with the arm and wrist extended. For example, common complaints include pain while shaking hands, lifting objects, using a computer mouse, or hitting a backhand in tennis (“tennis elbow”). Medial epicondylitis presents with pain during motions in which the arm is repetitively pronated or the wrist is flexed. This is also known as “golfer’s elbow” due to the motion of turning the hands over during the golf swing. For either, tenderness directly over the epicondyle is present, especially over the posterior aspect where the tendon insertion occurs. The proximal tendon and musculo-tendinous junction can also be sore. To confirm that the pain is due to tendinopathy, pain can be reproduced over the epicondyle with resisted wrist extension and third digit

extension for lateral epicondylitis and resisted wrist pronation and wrist flexion for medial epicondylitis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy.

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain. The mainstay of treatment is physical therapy exercises. The most important steps are to begin a good stretching program followed by strengthening exercises, particularly eccentric ones. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or long-standing symptoms, injections can be considered. A randomized trial showed improvement with corticosteroid injection at 1 month as well as evidence of decreased tendon thickness and Doppler changes but no improvement at 3 months. Treatments such as extracorporeal shock wave therapy and other injections have not shown clear long-term benefit. In a randomized controlled trial comparing platelet-rich protein (PRP) injection to controls ($n = 119$), the PRP-treated patients reported 55.1% improvement in their pain scores at 12 weeks compared to 47.4% in the active control group ($P = 0.163$). At 24 weeks, the PRP-treated patients reported 71.5% improvement in their pain scores compared to 56.1% in the control group ($P = 0.019$). Clinically significant improvement was 25% improvement of pain symptoms. The evidence suggests, however, that in most cases, PRP is a second-line treatment after physical therapy.

When to Refer

Patients not responding to 6 months of conservative treatment should be referred for an injection procedure (PRP or tenotomy), surgical debridement, or repair of the tendon.

2. Carpal Tunnel Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Pain, burning, and tingling in the distribution of the median nerve.
- ▶ Initially, most bothersome during sleep.
- ▶ Late weakness or atrophy of the thenar eminence.
- ▶ Can be caused by repetitive wrist activities.
- ▶ Commonly seen during pregnancy and in patients with diabetes mellitus or rheumatoid arthritis.

General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). The disorder may occur in fluid retention of pregnancy, in individuals with a history of repetitive use of the hands, or following injuries of the wrists. Carpal tunnel syndrome can also be a feature of many systemic diseases, such as rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis), myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly, and hyperparathyroidism. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified.

Clinical Findings

A. Symptoms and Signs

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to

identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. A **Tinel** or **Phalen** sign may be positive. A **Tinel sign** is tingling or shock-like pain on volar wrist percussion. The **Phalen sign** is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds. The **carpal compression test**, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests. Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens.

B. Imaging

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but estimated between 54% and 98%.

C. Special Tests

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which can occur in severe cases.

Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it should be treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities. The affected wrist can be splinted in the neutral position for up to 3 months, but a series of Cochrane reviews show limited evidence for splinting, therapeutic ultrasound, exercises, and ergonomic positioning. Oral corticosteroids or NSAIDs can also be tried. Methylprednisolone injections were found to have more effect at 10 weeks than placebo, but the benefits diminished by 1 year. A randomized, controlled trial showed both corticosteroid injection and surgery resolved symptoms but only decompressive surgery led to resolution of neurophysiologic changes.

Compared to trigger finger management, which usually includes injections, as many as 71% of patients with carpal tunnel directly undergo surgery without first getting injections. Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting longer than 12 months. Surgery can be done with an open approach or endoscopically, both yielding similar good improvements.

When to Refer

- If symptoms persist more than 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

3. Dupuytren Contracture

ESSENTIALS OF DIAGNOSIS

- ▶ Benign fibrosing disorder of the palmar fascia.
- ▶ Contracture of one or more fingers can lead to limited hand function.

General Considerations

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50 years of age, particularly in those of Celtic descent. The incidence is higher among alcoholic patients and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes plantar fibromatosis (10% of patients), Peyronie disease (1–2%), mediastinal and retroperitoneal fibrosis, and Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

Clinical Findings

Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand.

Treatment

If the palmar nodule is growing rapidly, injections of triamcinolone or collagenase into the nodule may be of benefit; the injection of collagenase *Clostridium histolyticum* lyses collagen thereby disrupting the contracted cords. Surgical options include open fasciectomy, partial fasciectomy, or percutaneous needle aponeurotomy and are indicated in patients with significant flexion contractures. Recurrence

is possible and there are more adverse events compared to nonoperative treatments. A multicenter study showed that collagenase injection and limited fasciectomy had similar improvements with contractures at the metacarpophalangeal joints, while surgery had better results for contractures involving the proximal interphalangeal joints.

When to Refer

Referral can be considered when one or more digits are affected by severe contractures, which interfere with everyday activities and result in functional limitations.

4. Bursitis

ESSENTIALS OF DIAGNOSIS

- ▶ Often occurs around bony prominences where it is important to reduce friction.
- ▶ Typically presents with local swelling that is painful acutely.
- ▶ Septic bursitis can present without fever or systemic signs.

General Considerations

Inflammation of bursae—the synovium-like cellular membranes overlying bony prominences—may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or OA. Bursitis can result from infection. The two common sites are the olecranon (Figure 41–1) and prepatellar bursae; however, others include subdeltoid, ischial, trochanteric, and semimembranous-gastrocnemius (Baker cyst) bursae. The bursitis can be septic. Aseptic bursitis is usually afebrile.

Clinical Findings

A. Symptoms and Signs

Bursitis presents with focal tenderness and swelling and is less likely to affect range of motion of the adjacent joint. Olecranon or prepatellar bursitis, for example, causes an oval (or, if chronic, bulbous) swelling at the tip of the elbow or knee and does not affect joint motion. Tenderness, erythema and warmth, cellulitis, a report of trauma, or evidence of a skin lesion are more common in septic bursitis but can be present in aseptic bursitis as well. Patients with septic bursitis can be febrile but the absence of fever does not exclude infection; **one-third of those with septic olecranon bursitis are afebrile**. A bursa can also become

▲ **Figure 41-1.** Chronic aseptic olecranon bursitis without erythema or tenderness. (Used, with permission, from Richard P. Usatine, MD in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

symptomatic when it ruptures. This is particularly true for Baker cyst, whose rupture can cause calf pain and swelling that mimic thrombophlebitis.

B. Imaging

Imaging is unnecessary unless there is concern for osteomyelitis, trauma or other underlying pathology. Ruptured Baker cysts are imaged easily by sonography or MRI. It may be important to exclude a deep venous thrombosis, which can be mimicked by a ruptured Baker cyst.

C. Special Tests

Acute swelling and redness at a bursal site calls for aspiration to rule out infection especially if the patient is either febrile (temperature more than 37.8°C) or has prebursal warmth (temperature difference greater than 2.2°C) or both. A bursal fluid white blood cell count of greater than 1000/mcL indicates inflammation from infection, rheumatoid arthritis, or gout. The bursal fluid of septic bursitis characteristically contains a purulent aspirate, fluid-to-serum glucose ratio less than 50%, white cell count more than 3000 cells/mcL, polymorphonuclear cells more than 50%, and a positive Gram stain for bacteria. Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds.

Treatment

Bursitis caused by trauma responds to local heat, rest, NSAIDs, and local corticosteroid injections. Chronic, stable olecranon bursa swelling usually does not require aspiration. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad. For chronic aseptic bursitis or when there are athletic or occupational demands, aspiration with intrabursal steroid injection can be performed. Aspiration of the olecranon bursa runs the risk of creating a chronic drainage site, which can be reduced by using a “zig-zag” approach with a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Ultrasound-guided aspiration and injection can improve the accuracy of the procedures. Treatment of a ruptured Baker cyst includes rest, leg elevation, and possibly injection of triamcinolone, 20–40 mg into the knee anteriorly (the knee compartment communicates with the cyst). However, corticosteroid injections in nonseptic bursitis have more complications and skin atrophy than simple symptomatic treatment.

Treatment for septic bursitis involves incision and drainage and antibiotics usually delivered intravenously.

When to Refer

- Surgical removal of the bursa is indicated only for cases in which repeated infections occur.
- Elective removal for persistent symptoms affecting activities of daily living can be considered.

Baumbach SF et al. Prepatellar and olecranon bursitis: literature review and development of a treatment algorithm. *Arch Orthop Trauma Surg.* 2014 Mar;134(3):359–70. [PMID: 24305696]

HIP

1. Hip Fractures

ESSENTIALS OF DIAGNOSIS

- ▶ Internal rotation of the hip is the best provocative diagnostic maneuver.
- ▶ Hip fractures should be surgically repaired as soon as possible (within 24 hours).
- ▶ Delayed treatment of hip fractures in older adults leads to increased complications and mortality.

General Considerations

Approximately 4% of the 7.9 million fractures that occur each year in the United States are hip fractures. There is a high mortality rate among older adult patients following

hip fracture, with death occurring in 8–9% within 30 days and in approximately 25–30% within 1 year. Osteoporosis, female sex, height greater than 5-foot 8-inches, and age over 50 years are risk factors for hip fracture. Hip fractures usually occur after a fall. High-velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with poor bone mineral density following repetitive loading activities.

► Clinical Findings

A. Symptoms and Signs

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee can also commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, the clinician can, with the patient supine, flex the hip to 90 degrees with the knee flexed to 90 degrees. The leg can then be internally and externally rotated to assess the range of motion on both sides. Pain with internal rotation of the hip is the most sensitive test to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle; the patient balances first on one leg, raising the non-standing knee toward the chest. The clinician can stand behind the patient and observe for dropping of the pelvis and buttock on the non-stance side. Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in patients with hip complaints, including examining for signs for sciatica.

Following displaced hip fractures, a thorough medical evaluation and treatment should be pursued to maximize the patients' ability to undergo operative intervention. Patients who are unable to get up by themselves may have been immobile for hours or even days following their falls. Thus, clinicians must exclude rhabdomyolysis, hypothermia, deep venous thrombosis, pulmonary embolism, and other conditions that can occur with prolonged immobilization. Delay of operative intervention leads to an increased risk of perioperative morbidity and mortality.

B. Imaging

Useful radiographic views of the hip include AP views of the pelvis and bilateral hips and frog-leg-lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to evaluate non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

► Treatment

Almost all patients with a hip fracture will require surgery and may need to be admitted to the hospital for pain control while they await surgery. **Surgery is recommended within the first 24 hours** because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, pressure injuries (formerly pressure ulcers), and deep venous thrombosis. High-volume centers have multidisciplinary teams (including orthopedic surgeons, internists, social workers, and specialized physical therapists) to comanage these patients, which improves perioperative medical care and expedites preoperative evaluation leading to reduced costs.

Stress fractures in active patients require a period of protected weight bearing and a gradual return to activities, although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are common complications after surgery. Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and pressure injuries. Supervised physical therapy and rehabilitation are important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence. Patients with hip fracture surgery when compared with elective total hip replacement have been shown to have higher risk of in-hospital mortality.

► Prevention

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly. There is strong evidence that bisphosphonates, denosumab, and teriparatide reduce fractures compared with placebo, with relative risk reductions of 0.60–0.80 for nonvertebral fractures. Nutrition (calcium and vitamin D intake) and bone health (bone densitometry, serum calcium and 25-OH vitamin D levels) should be reviewed with the patient (see Chapter 26). For patients with decreased mobility, systemic anticoagulation should be considered to avoid deep venous thrombosis (see Table 14–14). Fall prevention exercise programs are available for older adult patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

► When to Refer

- All patients in whom hip fracture is suspected.
- All patients with hip fracture or in whom the diagnosis is uncertain after radiographs.

2. Hip Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- ▶ Pain deep in the groin on the affected side.
- ▶ Swelling.
- ▶ Degeneration of joint cartilage.
- ▶ Loss of active and passive range of motion in severe OA.

General Considerations

In the United States, the prevalence of OA will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. Cartilage loss and OA symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of OA is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions. Femoroacetabular impingement, which affects younger active patients, is considered an early development of hip OA.

Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients complain of pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up from a chair. They may limp and develop a lurch during their gait, leaning toward the unaffected side as they walk to reduce pressure on the hip.

B. Imaging

An anterior-posterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip

are preferred views for evaluation of hip OA. Joint space narrowing and sclerosis suggest early OA, while osteophytes near the femoral head or acetabulum and subchondral bone cysts are more advanced changes. The sensitivity of radiographic hip OA for hip pain localized to the groin was 36.7%, specificity 90.5%, positive predictive value 6.0%, and negative predictive value 98.9%. However, not all patient with radiographic hip OA had hip or groin pain; the converse is also true because of the low sensitivity of the radiographs. After age 35, MRI of the hips already show labral changes in almost 70% of asymptomatic patients.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for patients with OA includes activity modification, proper footwear, therapeutic exercises, weight loss, and use of assistive devices (such as a cane). A 2014 randomized study found that physical therapy did not lead to greater improvement in pain or function compared with sham treatment in patients with hip OA. Analgesics may be effective in some cases. Corticosteroid injections can be considered for short-term relief of pain; however, hip injections are best performed under fluoroscopic, ultrasound, or CT guidance to ensure accurate injection in the joint.

B. Surgical

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms and functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Hip resurfacing surgery is a newer joint replacement technique. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Evidence to date suggests that hip resurfacing is comparable to total hip replacement and is a viable alternative for younger patients. The cumulative survival rate of this implant at 10 years is estimated to be 94%. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. In a systematic review of national databases, the average time to revision was 3.0 years for metal-on-metal hip resurfacing versus 7.8 years for total hip arthroplasty. Dislocations were more frequent with total hip arthroplasty than metal-on-metal hip resurfacing: 4.4 vs 0.9 per 1000 person-years, respectively.

Guidelines recommend prophylaxis for venous thromboembolic disease for a minimum of 14 days after arthroplasty of the hip or knee using warfarin, low-molecular-weight heparin, fondaparinux, aspirin, rivaroxaban, dabigatran, apixaban, or portable mechanical compression (see Table 14–14).

▶ When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

KNEE

1. Knee Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Effusion can occur with intra-articular pathology (eg, OA, meniscus and cruciate ligament tears).
- ▶ Acute knee swelling (due to hemarthrosis) within 2 hours may indicate ligament injuries or patellar dislocation or fracture.

▶ General Considerations

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation, infection, and degenerative changes. The knee is a hinge joint. The joint line exists between the femoral condyles and tibial plateaus. Separating and cushioning these bony surfaces is the lateral and medial meniscal cartilage, which functions as a shock absorber during weight bearing, protecting the articular cartilage. The patella is a large sesamoid bone anterior to the joint. It is embedded in the quadriceps tendon, and it articulates with the trochlear groove of the femur. Poor patellar tracking in the trochlear groove is a common source of knee pain especially when the cause is atraumatic in nature. The knee is stabilized by the collateral ligaments against varus (lateral collateral ligament) and valgus (medial collateral ligament) stresses. The tibia is limited in its anterior movement by the anterior cruciate ligament (ACL) and in its posterior movement by the posterior cruciate ligament (PCL). The bursae of the knee are located between the skin and bony prominences. They act to decrease friction of tendons and muscles as they move over adjacent bony structures. Excessive external pressure or friction can lead to swelling and pain of the bursae. The prepatellar bursae

(located between the skin and patella), and the pes anserine bursa (which is medial and inferior to the patella, just below the tibial plateau) are most commonly affected. Joint fluid, when excessive due to synovitis or trauma, can track posteriorly through a potential space, resulting in a popliteal cyst (also called a Baker cyst). Other structures that are susceptible to overuse injury and may cause knee pain following repetitive activity include the patellofemoral joint and the iliotibial band. OA of the knees is common after 50 years of age and can develop due to previous trauma, aging, activities, alignment issues, and genetic predisposition.

▶ Clinical Findings

A. Symptoms and Signs

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma, previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptom complaints include the following:

1. Presence of grinding, clicking, or popping with bending may be indicative of OA or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture, or patellar dislocation, especially if trauma is involved.
4. Lateral “snapping” with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened with bending and walking downstairs suggests issues with the patellofemoral joint, usually degenerative such as chondromalacia of the patella or OA.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A careful history coupled with a physical examination that includes observation, palpation, and range of motion testing, as well as specific tests for particular anatomic structures is frequently sufficient to establish a diagnosis. When there is a knee joint effusion caused by increased fluid in the intra-articular space, physical examination will demonstrate swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

Table 41–5 shows the differential diagnosis of knee pain, and Table 41–6 outlines possible diagnoses based on the location of pain.

Table 41–5. Differential diagnosis of knee pain.

Mechanical dysfunction or disruption
Internal derangement of the knee: injury to the menisci or ligaments
Degenerative changes caused by osteoarthritis
Dynamic dysfunction or misalignment of the patella
Fracture as a result of trauma
Intra-articular inflammation or increased pressure
Internal derangement of the knee: injury to the menisci or ligaments
Inflammation or infection of the knee joint
Ruptured popliteal (Baker) cyst
Peri-articular inflammation
Internal derangement of the knee: injury to the menisci or ligaments
Prepatellar or anserine bursitis
Ligamentous sprain

B. Laboratory Findings

Laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients (see Tables 20–2 and 20–3).

C. Imaging

Knee pain is evaluated with plain (weight-bearing) radiographs and MRI most commonly, but CT and ultrasound are sometimes useful.

An acute hemarthrosis represents bloody swelling that usually occurs within the first 1–2 hours following trauma. In situations where the trauma may be activity-related and

not a result of a fall or collision, the differential diagnosis most commonly includes ACL tear (responsible for more than 70% in adults), fracture (patella, tibial plateau, femoral supracondylar, growth plate [physeal]), and patellar dislocation. Meniscal tears are unlikely to cause large hemarthrosis.

2. Anterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ An injury involving an audible pop when the knee buckles.
- ▶ Acute swelling immediately (or within 2 hours).
- ▶ Instability occurs with lateral movement activities and going down stairs.

▶ General Considerations

The anterior cruciate ligament (ACL) connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. Its main function is to control anterior translation of the tibia on the femur. It also provides rotational stability of the tibia on the femur. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury, has acute swelling and difficulty with weight bearing and complains of instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-aged patients. Prepubertal and older patients usually sustain fractures instead of ligamentous injuries.

▶ Clinical Findings

A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a “stiff-knee” gait or quadriceps avoidance gait because of the instability. Patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing side-to-side maneuvers or descending stairs. The Lachman test (84–87% sensitivity and 93% specificity) is performed with the patient lying supine and the knee flexed to 20–30 degrees (Table 41–7). The clinician grasps the distal femur from the lateral side and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10- to 15-pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the ACL. The anterior drawer test (48% sensitivity and 87% specificity) is performed with the patient lying supine and the knee flexed to 90 degrees (Table 41–7). The clinician stabilizes the patient’s foot by sitting on it and grasps the proximal tibia with both hands around the calf

Table 41–6. Location of common causes of knee pain.

Medial knee pain
Medial compartment osteoarthritis
Medial collateral ligament strain
Medial meniscal injury
Anserine bursitis (pain over the proximal medial tibial plateau)
Anterior knee pain
Patellofemoral syndrome (often bilateral)
Osteoarthritis
Prepatellar bursitis (associated with swelling anterior to the patella)
“Jumper’s knee” (pain at the inferior pole of the patella)
Septic arthritis
Gout or other inflammatory disorder
Lateral knee pain
Lateral meniscal injury
Iliotibial band syndrome (pain superficially along the distal iliotibial band near lateral femoral condyle or lateral tibial insertion)
Lateral collateral ligament sprain (rare)
Posterior knee pain
Popliteal (Baker) cyst
Osteoarthritis
Meniscal tears
Hamstring or calf tendinopathy

and pulls anteriorly. A positive test finds ACL laxity compared with the unaffected side. The pivot shift test is used to determine the amount of rotational laxity of the knee (Table 41–7). The patient is examined while lying supine

with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.

Table 41–7. Knee examination.

Maneuver	Description
Inspection	Examine for the alignment of the lower extremities (varus, valgus, knee recurvatum), ankle eversion and foot pronation, gait, SEADS.
Palpation	Include important landmarks: patellofemoral joint, medial and lateral joint lines (especially posterior aspects), pes anserine bursa, distal iliotibial band and Gerdy tubercle (iliotibial band insertion).
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs), especially with flexion and extension of the knee normally 0–10 degrees of extension and 120–150 degrees of flexion.
	
Knee strength testing	Test resisted knee extension and knee flexion strength manually.
Ligament Stress Testing	
Lachman test	Performed with the patient lying supine, and the knee flexed to 20–30 degrees. The examiner grasps the distal femur from the lateral side, and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10–15 pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the anterior cruciate ligament.
	
Anterior drawer	Performed with the patient lying supine and the knee flexed to 90 degrees. The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds anterior cruciate ligament laxity compared with the unaffected side.
	

(continued)

Table 41-7. Knee examination. (continued)

Maneuver	Description
Valgus stress 	Performed with the patient supine. The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the medial collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee extension.
Varus stress 	The patient is again placed supine. For the right knee, the clinician should be standing on the right side of the patient. The left hand of the examiner should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the lateral collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

(continued)

Table 41–7. Knee examination. (continued)

Maneuver	Description
Meniscal Signs	
McMurray test	Performed with the patient lying supine. The clinician flexes the knee until the patient reports pain. For this test to be valid, it must be flexed pain-free beyond 90 degrees. The clinician externally rotates the patient's foot and then extends the knee while palpating the medial knee for "click" in the medial compartment of the knee or pain reproducing pain from a meniscus injury. To test the lateral meniscus, the same maneuver is repeated while rotating the foot internally (53% sensitivity and 59–97% specificity).
Modified McMurray	Performed with the hip flexed to 90 degrees. The knee is then flexed maximally with internal or external rotation of the lower leg. The knee can then be rotated with the lower leg in internal or external rotation to capture the torn meniscus underneath the condyles. A positive test is pain over the joint line while the knee is being flexed and internally or externally rotated.

(continued)

Table 41–7. Knee examination. (continued)

Maneuver	Description
Thessaly test 	Performed with the patient standing on one leg with knee slightly flexed. The patient is asked to twist the knee while standing on one leg. Pain can be elicited during twisting motion.

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee (“Segond” fracture) and is pathognomonic of an ACL injury. An ACL injury that avulsed the tibial spine can be seen in radiographs. MRI is the best tool to diagnose ACL tears and associated articular and meniscal cartilage issues. It has greater than 95% sensitivity and specificity for ACL tears.

Treatment

Most young and active patients will require surgical reconstruction of the ACL. Some data suggest reconstruction within 5 months has better outcomes. However, a small randomized trial suggested that acute ACL injuries can be treated nonoperatively and delayed ACL reconstruction had similar outcomes to acute ACL reconstructions but patients for whom the reconstruction is delayed have more cartilage or meniscus problems at the time of surgery. Common surgical techniques use the patient’s own tissue, usually the patellar or hamstring tendons (autograft) or a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL. Different patients groups experienced improved results with specific surgical graft choices. However, allografts do have a higher failure rate when compared with autografts. Recovery from surgery usually requires 6 months.

Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears.

When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (greater than 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

3. Collateral Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Caused by a valgus or varus blow or stress to the knee.
- ▶ Pain and instability in the affected area.
- ▶ Limited range of motion.

General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

Clinical Findings

A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests. The sensitivity of the tests is as high as 86–96%.

The **valgus stress test** is performed with the patient supine (Table 41–7). The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the MCL. The test should be performed at both 30 degrees and at 0 degrees of knee extension.

For the **varus stress test**, the patient is again placed supine (Table 41–7). For the right knee, the clinician should be standing on the right side of the patient. The clinician's left hand should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the LCL. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

The test results can be graded from 1 to 3. Grade 1 is when the patient has pain with varus/valgus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain. The knee is often unstable at both 30 degrees and 0 degrees of knee flexion.

B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out

fractures that can occur with collateral ligament injuries. Isolated MCL injuries usually do not require evaluation by MRI, but MRI should be used to evaluate possible associated cruciate ligament injuries. LCL or posterolateral corner injuries should have MRI evaluation to exclude associated injuries and to determine their significance.

Treatment

The majority of MCL injuries can be treated with protected weight bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion. A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear, but only with the knee locked in extension with a brace. The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. LCL injuries are less common but are usually associated with other ligament injuries (such as ACL and PCL). LCL injuries do not recover well with nonoperative treatment and usually require urgent surgical repair or reconstruction.

When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.
- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).

Pacheco RJ et al. Posterolateral corner injuries of the knee: a serious injury commonly missed. *J Bone Joint Surg Br.* 2011 Feb; 93(2):194–7. [PMID: 21282758]

4. Posterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Usually follows an anterior trauma to the tibia, such as a dashboard injury during a motor vehicle accident.
- ▶ The knee may freely dislocate and reduce.
- ▶ One-third of multi-ligament injuries involving the PCL have neurovascular injuries.

General Considerations

The posterior cruciate ligament (PCL) is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL

injuries have associated injuries to the posterolateral corner, MCL, and ACL. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries. **There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed.**

► Clinical Findings

A. Symptoms and Signs

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may complain of subjective “looseness” and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the “**sag sign**”; the patient is placed supine and both hips and knees are flexed to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia that is “sagging” posteriorly. The PCL ligament can also be examined using the **posterior drawer test**; the patient is placed supine with the knee flexed to 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee (90% sensitivity and 99% specificity). A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a false-positive test for an ACL injury. Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery.

B. Imaging

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

► Treatment

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction.

► When to Refer

- The patient should be seen urgently within 1–2 weeks.
- If the lateral knee is also unstable with varus stress testing, the patient should be assessed for a posterolateral corner injury, which may require an urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.

LaPrade CM et al. Emerging updates on the posterior cruciate ligament: a review of the current literature. *Am J Sports Med.* 2015 Dec;43(12):3077–92. [PMID: 25776184]

5. Meniscus Injuries

ESSENTIALS OF DIAGNOSIS

- Patient may or may not report an injury.
- Joint line pain and pain with deep squatting are the most sensitive signs.
- Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

► General Considerations

The menisci act as shock absorbers within the knee. Injuries to a meniscus can lead to pain, clicking, and locking sensation. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).

► Clinical Findings

A. Symptoms and Signs

The patient may have an antalgic (painful) gait and difficulty with squatting. He or she may complain of catching or locking of the meniscal fragment. Physical findings can include effusion or joint line tenderness. Patients can usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Provocative tests, including the **McMurray test**, the **modified McMurray test**, and the **Thessaly test**, can be performed to confirm the diagnosis (Table 41–7). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a “duck walk”).

B. Imaging

Radiographs are usually normal but may show joint space narrowing, early OA changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity). High signal through the meniscus (bright on T2 images) represents a meniscal tear.

► Treatment

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar for patients with mild knee OA, including analgesics and physical therapy for strengthening and core stability. A randomized controlled trial showed that physical therapy compared to arthroscopic

partial meniscectomy had similar outcomes at 6 months. However, 30% of the patients who were assigned to physical therapy alone underwent surgery within 6 months.

Randomized studies have shown that arthroscopic surgery has no benefit over sham operations in patients who have degenerative meniscal tears, especially with imaging showing signs of osteoarthritis. Another randomized controlled trial found that patients with degenerative meniscus tears but no signs of arthritis on imaging treated conservatively with supervised exercise therapy had similar outcomes to those treated with arthroscopy with 2 year follow up. There is crossover between the groups; patients can be treated with supervised exercise therapy first, and if they do not respond to nonoperative treatment, they can undergo meniscus surgeries. Acute tears in young and active patients with clinical signs of internal derangement (catching and swelling) and without signs of arthritis on imaging or patients with acute mechanical locking with a displaced meniscus can be best treated arthroscopically with meniscus repair or debridement. There is also growing evidence that untreated meniscus root tears can lead to accelerated osteoarthritic changes. Surgical treatment before cartilage breakdown is recommended for acute meniscus root injuries.

When to Refer

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears, are amenable to meniscal repair surgery.
- If the patient has MRI confirmation of acute meniscus root injuries.

6. Patellofemoral Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Pain experienced with bending activities (kneeling, squatting, climbing stairs).
- ▶ Lateral deviation or tilting of the patella in relation to the femoral groove.

General Considerations

Patellofemoral pain, also known as anterior knee pain, chondromalacia, or “runner’s knee,” describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. The patella engages the femoral trochlear groove with approximately 30 degrees of knee flexion. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.

Clinical Findings

A. Symptoms and Signs

Patients usually complain of pain in the anterior knee with bending movements and less commonly in full extension. Pain from this condition is localized under the kneecap but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after a trauma or after repetitive physical activity, such as running and jumping. When maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless there are articular cartilage defects or if OA changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. For example, the clinician can use one hand to move the patella laterally, and use the fingertips of the other hand to palpate the lateral undersurface of patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the kneecap is consider normal; greater than one-half the diameter suggests excessive mobility). The **apprehension sign** suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally. The **patellar grind test** is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) patients whose ligaments and patella are too loose (hypermobility); (2) and patients who have soft tissues that are too tight leading to excessive pressure on the joint.

Evaluation of the quadriceps strength and hip stabilizers can be accomplished by having the patient perform a one-leg squat without support. Patients who are weak may display poor balance, with dropping of the pelvis (similar

to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for OA or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

► Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking. There is consistent evidence that exercise therapy for patellofemoral pain syndrome may result in clinically important reduction in pain and improvement in functional ability. Lower quality research supports that hip and knee exercises are better than knee exercises alone. Strengthening the quadriceps and the posterolateral hip muscles such as the hip abductors that control rotation at the knee should be recommended. Support for the patellofemoral joint can be provided by use of a patellar stabilizer brace or special taping techniques (McConnell taping). Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high-arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves, and hip flexors.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery.

► When to Refer

Patients with persistent symptoms despite a course of conservative therapy.

7. Knee Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- Degeneration of joint cartilage.
- Pain with bending or twisting activities.
- Swelling.
- Loss of active and passive range of motion in severe OA.

► General Considerations

In the United States, the prevalence of OA will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. The incidence of knee OA in the United States is 240 per 100,000 person-years.

Cartilage loss and OA symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of OA is often multifactorial including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

► Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee OA have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities, and going up and down stairs. Swelling, limping, and pain while sleeping are common complaints with OA, especially as it progresses.

B. Imaging

The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, including ischemic osteonecrosis of the knee.

► Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although

symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with OA includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high-impact activities. Optimal exercise programs for knee OA should focus on improving aerobic capacity, quadriceps muscle strength, or lower extremity performance. Ideally, the program should be supervised and carried out three times a week.

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartmental OA in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

There are several oral and intra-articular pharmacologic options. Treatments that have been studied include oral acetaminophen, diclofenac, ibuprofen, naproxen, celecoxib, and intra-articular corticosteroids and hyaluronic acid. All treatments except acetaminophen showed clinically significant improvement in pain. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and adherence. The cyclooxygenase (COX)-2 inhibitor celecoxib is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential cardiovascular risk, celecoxib should be reserved for carefully selected patients. Topical NSAIDs or capsaicin can be effective in the treatment of OA, since they avoid many of the traditional NSAID complications. Opioids can be used appropriately in patients with severe OA (see Chapter 5). Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for OA. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in OA. However, they have minimal side effects and may be appropriate if the patient experiences subjective benefit.

Knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. Viscosupplementation by injections of hyaluronic acid-based products is controversial. Because reviews suggest that viscosupplementation has a questionably clinically relevant effect size, and has an increased risk of adverse events, the American Academy of Orthopedic Surgeons has recommended that viscosupplementation should not be used in the treatment of knee OA. However, the American College of Rheumatology's 2012 OA guidelines recommend the use of intra-articular hyaluronic acid injection for the treatment of OA of the knee in adults. Platelet-rich plasma injections contain high concentration of platelet-derived growth factors, which regulate some biologic processes in tissue repair. A meta-analysis of 10 studies demonstrated that platelet-rich plasma injections reduced pain in patients with knee OA more efficiently than placebo and hyaluronic acid injections. However, 9 of

the 10 studies had a high risk of bias, and the underlying mechanism of biologic healing is unknown. An FDA safety and efficacy study showed that leukocyte-poor PRP autologous conditioned plasma improved overall Western Ontario and McMaster Universities Arthritis Index scores by 78% from the baseline score after 12 months, compared to 7% for the placebo group, though the sample size was small (30 patients).

B. Surgical

Two randomized trials demonstrated that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of OA. Joint replacement surgeries are effective and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life. The number of total knee arthroplasty procedures jumped 162% from 1991 to 2010, along with an increase in complications and hospital readmissions. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates; however, major improvements have yet to be demonstrated.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartmental OA, who would benefit from delaying total knee replacement. Knee joint replacement surgery has been very successful in improving outcomes for patient with end-stage OA. Long-term series describe more than 95% survival rate of the implant at 15 years.

▶ When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

ANKLE INJURIES

1. Inversion Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- ▶ Localized pain and swelling.
- ▶ The majority of ankle injuries involve inversion injuries affecting the lateral ligaments.
- ▶ Consider chronic ankle instability or associated injuries if pain persists for longer than 3 months following an ankle sprain.

General Considerations

Ankle sprains are the most common sports injuries seen in outpatient clinics. Patients usually report “turning the ankle” during a fall or after landing on an irregular surface such as a hole or an opponent’s foot. The most common mechanism of injury is an inversion and plantar flexion sprain, which injures the anterior talofibular ligament (ATF) ligament rather than the calcaneofibular ligament (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in Table 41–8. Women appear to sustain an inversion injury more frequently than men. Up to 43% of ankle sprains can still have problems at 6 months, even with physical therapy, which makes proper early treatment of ankle sprains important.

Clinical Findings

A. Symptoms and Signs

The usual symptoms following a sprain include localized pain and swelling over the lateral aspect of the ankle, difficulty weight bearing, and limping. The patient’s ankle may feel unstable. On examination, there may be swelling or bruising over the lateral aspect of the ankle. The anterior, inferior aspect below the lateral malleolus is most

often the point of maximal tenderness consistent with ATF and CF ligament injuries. The swelling may limit motion of the ankle. Special stress tests for the ankle include the **anterior drawer test**; the clinician keeps the foot and ankle in the neutral position with the patient sitting, then uses one hand to fix the tibia and the other to hold the patient’s heel and draw the ankle forward. Normally, there may be approximately 3 mm of translation until an endpoint is felt. A positive test includes increased translation of one foot compared to the other with loss of the endpoint of the anterior talofibular ligament.

Another stress test is the **subtalar tilt test**, which is performed with the foot in the neutral position with the patient sitting. The clinician uses one hand to fix the tibia and the other to hold and invert the calcaneus. Normal inversion at the subtalar joint is approximately 30 degrees. A positive test consists of increased subtalar joint inversion greater than 10 degrees on the affected side with loss of endpoint for the calcaneofibular ligament. In order to grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury.

B. Imaging

Routine ankle radiographic views include the AP, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. **Ottawa Ankle Rules** are clinical prediction rules to guide the need for radiographs and have a 97% sensitivity and 99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleoli demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

Table 41–8. Injuries associated with ankle sprains.

Ligaments

Subtalar joint sprain
Sinus tarsi syndrome
Syndesmotric sprain
Deltoid sprain
Lisfranc injury

Tendons

Posterior tibial tendon strain
Peroneal tendon subluxation

Bones

Osteochondral talus injury
Lateral talar process fracture
Posterior impingement (os trigonum)
Fracture at the base of the fifth metatarsal
Jones fracture
Salter fracture (fibula)
Ankle fractures

Treatment

Immediate treatment of an ankle sprain follows the MICE mnemonic: *modified activities, ice, compression, and elevation*. Subsequent treatment involves protected weight bearing with crutches and use of an ankle stabilizer brace, especially for grade 2 and 3 injuries. **Early motion is essential, and patients should be encouraged to do home exercises or physical therapy.** Proprioception and balance exercises (eg, “wobble board”) are useful to restore function to the ankle and prevent future ankle sprains. Regular use of an ankle support with activities can reduce the risk of lateral ankle sprains. Chronic instability can develop after acute ankle sprain in 10–20% of people and may require surgical stabilization with ligament reconstruction surgery.

► When to Refer

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.
- No response after more than 3 months of conservative treatment.
- Suspicion of associated injuries.

2. Eversion (“High”) Ankle Sprains

- Severe and prolonged pain.
- Limited range of motion.
- Mild swelling.
- Difficulty with weight bearing.

► General Considerations

A syndesmotom injury or “high ankle” sprain involves the anterior *tibiofibular* ligament in the anterolateral aspect of the ankle, superior to the anterior *talofibular* (ATF) ligament. The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

► Clinical Findings

A. Symptoms and Signs

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiofibular ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiofibular ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotom ligament injury and associated

fracture known as a “maisonneuve fracture.” There is often some mild swelling in this area, and the patient may or may not have an ankle effusion. The patient usually has limited range of motion in all directions. To perform the **external rotation stress test**, the clinician fixes the tibia with one hand and grasps the foot in the other with the ankle in the neutral position. The ankle is then dorsiflexed and externally rotated, reproducing the patient’s pain. (**Note:** The patient’s foot should have an intact neurovascular examination before undertaking this test.)

B. Imaging

Radiographs of the ankle should include the AP, mortise, and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotom ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an AP and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. Radiographs during an external rotation stress test may visualize instability at the distal tibiofibular joint. MRI is the best method to visualize injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

► Treatment

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight bearing initially.

► When to Refer

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint. Screw fixation remains the gold standard, although newer techniques with bioabsorbable constructs are emerging.

Comprising roughly 4% of adult women in the United States, lesbian and bisexual women are considered a medically underserved population in the United States by the National Academy of Medicine. Furthermore, since 2016, lesbian and bisexual women—as sexual minorities—are considered a health disparity population by the US National Institutes of Health. Professional medical organizations, such as the American College of Physicians, have published position papers to educate and make recommendations on achieving equity for lesbian, gay, bisexual, and transgender (LGBT) individuals in the health care system. Barriers to care include both personal and structural. Personal barriers may include the patient's experience of disrespectful behavior and discrimination by health care providers and staff members and feeling threatened or experiencing a refusal of treatment due to sexual orientation, which may cause delay or avoidance of care. Structural barriers may include social stigma and even abject violence, financial challenges caused by decreased prevalence of insurance coverage (eg, many employers do not provide same-sex partner benefits), and the lack of trained providers to care for lesbian and bisexual women. Even when lesbian and bisexual women do seek medical care, it may not be appropriately targeted to the unique issues of this underserved population and therefore less effective. In the United States, women in same-sex couples are less likely to get nonurgent medical care when needed, see a specialist, and feel that doctors spent enough time with them. Lesbian and bisexual women in the United States are also less likely to have primary care providers. A study in Lebanon noted that significantly more sexual minority women reported having trouble accessing health care than heterosexual women, and a meta-analysis of southern African countries outlined the unique health challenges faced by sexual minority women, including social exclusion and invisibility, criminalization, and systematic homophobic sexual assault. There is a lack of systematic medical knowledge, however, about the care and understanding of lesbian and bisexual women. The

World Health Organization (WHO) recognized this deficiency, stating that the limitation in available data “points to the fact that LGBT people often experience poorer health outcomes than the general population and face barriers to health care that profoundly affect their overall health and well-being.”

► Importance of Asking & Knowing Patients' Sexual Orientation

Having a sexual minority sexual orientation has been shown to be associated with health disparities. It is also central to individuals' identities, social structures, and behaviors. For these reasons, asking and knowing about a patient's sexual orientation correlates with better health and health care outcomes.

One study compared sexual minority women (women who identify as lesbian, gay, bisexual, or queer) with heterosexual women; results found that sexual minority

women reported greater satisfaction with their health care provider when the clinician assessed or knew their sexual orientation. Furthermore, asking sexual minority women about their sexual orientation led to normalization of non-majority sexual orientation status and enhanced perception of the doctor-patient relationship. Conversely, not inquiring, proposed by many clinicians to avoid offense, led to a feeling of silencing. Although many providers do not ask and are concerned that patients will not respond favorably to questions about sexual orientation, very high acceptability among patients has been demonstrated in a review of studies looking at patient acceptability of questions. In a study documenting the discordance between patient and provider perceptions, 78% of providers thought that patients (both sexual minority and sexual majority) would refuse to disclose their sexual identities, while only 10% of patients reported that they would not disclose their sexual orientation. The degree of discordance, though, may not be the same across all groups; in one study in New York City, 13% of lesbian women and 33% of bisexual women did not disclose their sexual orientation or same-sex behaviors to their health care providers. Nondisclosure of sexual orientation was related to poorer psychological well-being at 1-year follow-up, independent of baseline psychological well-being. Nondisclosure by lesbian and bisexual women was more likely if she was a member of an ethnic minority group, had low educational level, had children, had higher level of internalized homonegativity, and did not have a history of a medical condition. Rates for continuing medical care were significantly decreased if there was a negative interaction with the clinician as perceived by sexual minority African-American female patients in one study: 34% of the patients did not see a doctor the next time they were ill. A solid therapeutic relationship can mitigate the difficulty in disclosure of sexual orientation.

Disclosure in the electronic medical record has been advocated in the United States by the Institute of Medicine and Joint Commission. However, there are risks for lesbian and bisexual women with having their sexual orientation documented in the medical record. Examples of such risks include loss of job (in 28 states in the United States a person can legally be fired on the basis of sexual orientation, and same-sex sexual relations are criminalized in over 72 countries) and fear of discrimination within the medical system (where 18% of lesbian, gay, bisexual, transgender, and queer [LGBTQ] individuals avoid seeking health care given concerns about identity-based discrimination).

Disclosure goes beyond establishing rapport but directly enhances clinical interactions. In an experimental design, researchers randomly assigned LGB patients to read heteronormative (wherein the assumption is heterosexuality) and nonheterosexual vignettes and then asked participants to indicate the level of health-related information they would disclose. Exposure to nonheterosexual health care vignettes positively correlated with more complete information disclosure. However, disclosure to health care providers, despite having positive outcomes, can still be challenging. Facilitating meaningful disclosure is aided by establishing a strong therapeutic rapport with patients and critical self-assessment and modification of health care

providers' own heteronormative value systems and communication styles. Changing the culture of medicine to welcome lesbian and bisexual women in one's medical practice and applying one's knowledge about the specific health issues of this underserved population is essential to their achieving health equity.

Methods of Identification of Sexual Orientation in Practice

How does a clinician identify the lesbian and bisexual women during an office visit? Some patients voluntarily self-disclose their sexual orientation without prompting, some respond to intake forms, others to direct questioning, and some never disclose. How a clinician assesses sexual orientation depends on practice type, specialty, care location, and population. One approach is to assess with questionnaires or patient portals on an electronic medical record prior to a first new patient encounter. A good question regarding sexual orientation to incorporate in the history form is

"Do you think of yourself as lesbian, gay, or homosexual? Straight or heterosexual? Bisexual? Something else, please describe." Having answer options such as "Don't know" and "Choose not to answer" can also be included on the form. The Fenway Institute, which specializes in LGBT Health and Health Care, proposes using the following statement and follow-up questions:

"I am going to ask you some questions about your sexual health and sexuality that I ask all my patients. The answers to these questions are important for me to know how to help keep you healthy. Like the rest of this visit, this information is strictly confidential."

Evidence suggests that most individuals are ready and willing to disclose to sensitive providers who make it clear the intent behind their questions. Additional questions include the following:

"Do you have a partner or a spouse?" or "Are you currently in a relationship?"

"Are you sexually active?"

"When was the last time you had sex?"

"What are the genders of your sexual partner (s)?"

"How many sexual partners have you had during the last year?"

"Do you have any desires regarding sexual intimacy that you would like to discuss?"

Rather than considering this a one-time intervention, it should rather be thought of as a process that is assessed over time and at critical junctures and changes in health status.

Part of identifying and serving lesbian and bisexual women is to create a welcoming clinical space where each person is cared for and respected for **all** of who they are—including their sexual orientation. One exercise is to look at clinic materials (ie, signs, posters, brochures, magazines, intake forms etc.) and see if materials presume heterosexual sexual behavior interactions or identities. Often, materials discussing sex, family planning, conception, pregnancy, and birth presume heterosexual interactions. If so, find or create more inclusive materials to replace them.

The Association of American Medical Colleges (AAMC) has created a series of online videos that highlight history-taking that includes assessments of sexual orientation, gender identity, and sexual practices: <https://www.aamc.org/initiatives/diversity/450606/clinicalvignettes.html>. The AAMC has produced noteworthy videos about family counseling and coming out (<https://www.aamc.org/initiatives/diversity/450466/family-counseling.html>), gender and sexual history taking (<https://www.aamc.org/initiatives/diversity/450468/gender-and-sexual-history1.html> and <https://www.aamc.org/initiatives/diversity/450470/gender-and-sexual-history2.html>), and ineffective history taking (<https://www.aamc.org/initiatives/diversity/450472/ineffective-history-taking.html>).

▶ Understanding Differences Between Orientation, Identity, & Behaviors

Who are lesbian and bisexual women? Lesbian women are romantically, emotionally, and sexually attracted to, and/or engage sexually with other women. Bisexual women are romantically, emotionally, and sexually attracted to, and/or engage sexually with both men and women. These definitions, though, may obscure differences between sexual orientation and sexual behaviors and also presume that there are only two genders. Also, for most people, the assumption is that the above statements refer to cisgender women, individuals whose gender identity as a woman is consistent with a female sex assigned at birth. However, transgender women (individuals whose gender identity as a woman is different than their male sex assigned at birth) often have lesbian and bisexual identities and behavioral patterns as well. However, there is scant research on the experiences of transgender women who are lesbian and bisexual, so almost all of the data subsequently discussed presumes cisgender lesbian and bisexual women.

For lesbian and bisexual women, differences between identity and behavior are common. For example, among those who identify as lesbian women, 70% are sexually active exclusively with other women (women who have sex with women [WSW]), and 30% are sexually active with women and men (women who have sex with women and men [WSWM]). Assessment of behavior in addition to identity is critical to delineate patterns of risk and opportunities for intervention, such as counseling about prevention of an unintended pregnancy while understanding health modifying features like social support structures. In the United States, about 9% of women overall report ever having a same-sex partner, with 15% reporting this sexual activity in the 20- to 24-year-old cohort. Ten percent of self-identified lesbians have never been sexually active with men ("lifetime lesbians") and 90% of lesbians have been sexually active with men in the past ("adult lesbians"). Lesbian and bisexual women are diverse in age, ethnicity, location, income, and educational level. Of those women who currently identify as bisexual in orientation, they may be in a current sexual relationship with a man but have a history of being in sexual relationships with women, or they may have both male and female sexual partners concurrently. About 70% of lesbian women are in couple relationships and 59% of bisexual women and 31% of lesbian women have children.

Part of appreciating and accurately assessing sexual orientation is delineating it from gender identity (a person's internal sense of maleness, femaleness, or another gender) and from gender expression (how gender is presented using clothes and mannerisms, for example) and how this is yet again different from person's sex assigned at birth (the physiologic, anatomic, and reproductive structures with which one was born).

Many transgender women have lesbian or bisexual sexual orientations. It is important to understand that sexuality (including identity, attraction, and behaviors), like gender identity and gender expression, is a spectrum and may vary over time with age, cultural context, and region.

Structural barriers in communities also contribute to health disparities (eg, community norms, institutional policies). Living in communities with high levels of anti-gay prejudice increases the risk of premature mortality for all sexual minorities, since LGBT people living in communities with high levels of anti-gay prejudice experience a shorter life expectancy by 12 years with contributions of suicide, homicide/violence, and cardiovascular disease (CVD). To help decrease this all-cause mortality in lesbian and bisexual women, clinicians can educate themselves about health issues of this population and focus on prevention as well as advocate for community and institutional changes.

▶ Health Disparities Affecting Lesbian & Bisexual Women

Health disparities exist across the life span for lesbian and bisexual women compared to heterosexual women. The following are increased among lesbian and bisexual women: childhood physical abuse in the home, childhood

sexual abuse, substance use including alcohol and tobacco, risk of chlamydial infection as teens and young adults, risk of sexual assault, prevalence of depression, rate of disabilities, body mass index (BMI), intimate partner violence, threats and violence outside the home, risk of asthma, and risk of CVD. It has been suggested that rates of human papillomavirus (HPV) are higher among lesbian and bisexual women due to decreased rates of HPV immunization. Sexual dysfunction for lesbian and bisexual women is at a rate lower than or equal to that of heterosexual women. A high risk of sexual dysfunction can be detected by a single question of “bother” regarding sexual function: “Are you bothered by issues of sexual function?” Studies of elders in the Irish LGBT community reveal concerns about residential care outside of their own home as well as respect by health professionals; similarly, there are concerns about home services for lesbian and bisexual women in Canada. Lesbian and bisexual women have fewer children available to help them as they age compared to heterosexual women. Therefore, it is critical that health care providers identify health decision makers for all patients including lesbian and bisexual women who may have more “family of choice” members versus “family of origin” members who may be estranged. This is especially important as same-sex marriage is not allowed in many countries and is still considered socially unacceptable in many areas of the United States. To avoid conflict during critical decision-making moments, the health decision maker needs to be identified on the medical record, after a private conversation with the patient. In one survey, only about 50% of same-sex couples who desired their partner to be the health decision maker had appropriate forms, and even if married, advance directives should be completed given past visitation denials. Many notable legal cases, including that of Sharon Kowalski and Karen Thompson, have documented the struggles that same-sex partners can face regarding visitation and appropriate recognition during end-of-life care or critical medical decision making when these documents have not been completed. Elder abuse screening also needs to be done, since the incidence is unknown but does occur.

Lawton A et al. End-of-Life and advance care planning considerations for lesbian, gay, bisexual and transgender patients #275. *J Palliat Med*. 2014 Jan;17(1):106–8. [PMID: 24351127]
Reiter PL et al. HPV infection among a population-based sample of sexual minority women from USA. *Sex Transm Infect*. 2017 Feb;93(1):25–31. [PMID: 27165699]

► Prevention of CVD

The risk of CVD is higher in sexual-minority women. Though many studies lack objective measures such as biomarkers, a systematic review demonstrated greater CVD among sexual minority women. Ultimately this outcome seemed most influenced by societal conditions (ie, cumulative minority stress) that exert negative effects on CVD risk. In one study, lesbian and bisexual women were 14% older in vascular terms than their chronological age, which was 6% greater than that of their heterosexual counterparts and the risk was not fully explained by excessive smoking or alcohol use. When the effect of five stressful life events

(physical abuse, sexual abuse and forced sex, homelessness, school expulsion, death of a parent), was compared between LGB women and heterosexual women, higher cardiometabolic risk scores were found in LGB women, even after controlling for demographic factors, socioeconomic status, health behaviors, and self-reported illness. Although many studies report similar hypertension prevalence among lesbian, bisexual, and heterosexual women, more recent work has described higher prevalence of hypertension among sexual minority women when compared with heterosexual counterparts.

The leading five modifiable risk factors for CVD are smoking, physical inactivity, obesity, elevated lipid levels, and diabetes. Three of these factors (smoking, physical inactivity, and obesity) have a higher prevalence in lesbian and bisexual women.

► Smoking

Cigarette smoking is more prevalent among lesbian and bisexual women than in heterosexual women. While estimates vary, the National Adult Tobacco Survey noted 22% of lesbian women and 32% of bisexual women smoke compared with 13% of heterosexual women. The National Health Interview Survey noted that lesbian and bisexual women are also heavier smokers. The tobacco industry's well-documented targeted marketing to LGBT groups and the use of cigarette smoking to decrease social stress are probable factors. Significant racial and ethnic differences exist with Asian and Pacific Islander lesbian and bisexual women, who have four times higher odds of smoking than heterosexual Asian and Pacific Islander women. In high school, LGB adolescents reported a higher prevalence of daily cigarette use (22%) compared with heterosexual youth (11%). Protective factors against smoking behaviors for young LGB women included LGBT community connections. Another study demonstrated that though desire to quit did not differ between sexual minority women and their heterosexual counterparts, cessation attempts did differ, suggesting that clinicians need to customize cessation interventions for sexual minority women.

Traditional smoking cessation programs and targeted LGBT programs are effective for LGBT people. A review of smoking cessation programs for LGBTI (Intersex) people found that with cultural modifications for LGBTI people, 61% had quit at the end of interventions and this stabilized to 39% at 3–6 months. The LGBT community in Ireland has very high tobacco use and exposure to secondhand smoke. Attention should be paid to messaging about smoking warnings as not all messages are perceived as equally

effective by sexual minorities when compared with heterosexual people. Encourage patients to check with their community or online resources for smoking cessation programs and encourage participation in LGBTQ tailored programs, if available.

▶ Activity & Body Weight

Data regarding obesity and overweight prevalence in lesbians and bisexual women are mixed. Many studies, though, including an analysis of over 60,000 women in the National Health Interview Survey find that being a sexual minority woman is associated with an elevated BMI compared to heterosexual women. The prevalence of obesity may not be uniform across racial and ethnic groups. The odds of obesity among lesbians in the following groups differed when compared with heterosexuals in the same racial group: Latina lesbians 1.39 (95% CI, 1.20, 1.61), Asian and Pacific Islander lesbians 1.22 (95% CI, 0.76, 1.94) vs American Indian/Alaska Native lesbians 2.06 (95% CI, 1.56, 2.70). Findings also differed between bisexual and lesbian women within racial and ethnic minority groups.

Obesity and overweight may start at a young age in lesbian and bisexual youth and they may conceptualize their weight differently than heterosexual peers. Among adolescents in the Massachusetts Youth Risk Behavior Survey, lesbian and bisexual females were more likely to self-perceive as being of healthy weight or underweight despite being overweight or obese, and 33% engaged in hazardous weight control behaviors. A high school-based study (grades 9–12) in 22 Wisconsin schools revealed that sexual minority female youth, compared to their heterosexual counterparts, were less likely to participate in team sports, and in college, only one of three lesbian, bisexual, and queer women met national physical activity guidelines. Overweight and obesity may also develop as women age. When women were followed longitudinally, lesbian women were more at risk for developing obesity than heterosexual women. Studies of physical activity have found that while there may be greater physical activity and fitness among

some sexual minority women, so is increased sedentary time. There have also been findings of differences in dietary patterns between lesbian, bisexual, and heterosexual women.

Studies about successful weight intervention programs for lesbian and bisexual women are emerging. A US Office on Women's Health-funded study of a 12-session intervention program targeted to lesbian and bisexual women over 60 years of age found the program to be efficacious with a 3.7% decrease in waist circumference. Further, randomized interventions using mindfulness, healthy eating, and physical activity in obese lesbian and bisexual women were effective in reducing low-density lipoprotein cholesterol and increasing healthy eating. Focus groups have identified themes related to weight for lesbian and bisexual women: aging, physical and mental health status, community norms, subgroup differences, family and partner support, and awareness and tracking of diet and physical activity. Participants expressed feeling unprepared for age-related changes to their health and voiced interest in interventions addressing these issues. Findings from focus groups included (1) a preference for interventions focusing on promoting health and full life participation rather than on weight loss only, (2) cultural norms within the lesbian community that were accepting of larger body types, (3) an increased awareness in older age that the larger body size may exacerbate chronic health problems such as knee pain, and (4) the importance of social support and group structures in initiating and maintaining healthy behaviors.

▶ Prevention of Pulmonary Disease

Pulmonary disease has not been rigorously studied in lesbians or bisexual women. However, with the increased prevalence of smoking in these communities compared to heterosexual women, there may be more acute respiratory illness, chronic pulmonary disease, and lung cancer—especially with increasing age. Lesbian women have a higher prevalence of lifetime and current asthma, even when statistical models are used to correct for current and

past smoking and obesity, all of which are increased in lesbian and bisexual women. Overweight or obese lesbian and bisexual women are more than seven times more likely to report current asthma and three times more likely to report lifetime asthma than lesbian and bisexual women who are not overweight or obese.

Prevention of Sexually Transmitted Infections

Sexually transmitted infections (STIs) occur in lesbian and bisexual women in all countries, but little population-based data are available to delineate precise risks. Asking about sexual *behaviors* in addition to sexual *identity* is key to identifying STI risk and advising appropriate testing since risk may vary by specific sexual practice (eg, digital-vaginal, vaginal-vaginal, digital-anal, oral-vaginal, oral-anal contact) and the specific pathogen. WSW are noted by the Centers for Disease Control and Prevention (CDC) to have diverse sexual practices and that use of barrier protection in examined studies (eg, use of gloves, dental dams) was ubiquitously low.

Chlamydial infections were higher in 14- to 24-year-old women who reported same-sex behavior when attending family planning clinics in the US Pacific Northwest compared to women who reported exclusively heterosexual behavior. Possible explanations for this observation include differences in these groups' use of reproductive health care services, infrequent use of barrier methods to prevent STI transmission with female partners, trends toward higher-risk behaviors, and different social network characteristics. Untreated chlamydial infection places a woman's future fertility at risk due to potential tubal occlusion. Some women who have a chlamydial infection do not have symptoms. Secondary sequelae of chlamydia include intra-abdominal abscesses, chronic pain, and the need for multiple surgeries. Regardless of sexual orientation, the CDC recommends annual *Chlamydia trachomatis* (and *Neisseria gonorrhoeae*) screening from the age of first sexual activity to the age of 25 years for all women.

It is important to ask lesbian and bisexual women about specific sexual practices, as some practices may carry a higher risk of STIs than others, although there has been little research on sexual practices and the risk of STIs in this population. Thus, inferences are drawn from heterosexual prevention of these infections. "Safer Sex Kits" have occasionally been distributed to WSW and WSWM to decrease the risk of STIs, but intervention effectiveness has not been studied. These kits often include dental dams to prevent

transmission of bacteria and viruses from oral sex, but the efficacy of dental dams for this function has not been studied. Female latex condoms and latex gloves may provide better protection against infectious transmission from oral sex since latex has been studied as a barrier for prevention of HIV and other STIs. Exchange of blood should be avoided as much as possible, especially in HIV-discordant lesbian couples, since viral genotype analysis has confirmed that HIV can be transmitted sexually between women. The clinician should encourage both partners in new lesbian couples to have HIV screening prior to sexual contact and recommend barrier protection for 6 months until the couple is again screened to verify that their HIV status is still negative. If the couple is monogamous, barrier precautions do not need to be continued. However, lesbian and bisexual women may not follow this advice, since many feel they are at low risk for HIV, which may be correct, but data are lacking. About 20–50% of lesbian women use sexual aids (eg, vibrators, dildos, or other sexual toys); these should not be shared with partners and should be cleaned after use. The HPV can remain on these sexual aids for up to 24 hours after use, even after standard cleaning. Some lesbian and bisexual women are sex workers or have had sexual relationships with high-risk male sexual partners (sometimes gay male friends) and are at increased risk for STIs. Current CDC guidelines recommend that all women should be tested once in their lifetime for HIV, and then repeated according to risk factors.

The herpes simplex virus (HSV) can be transmitted sexually between women. The same precautions regarding the transmission of HSV should be provided to lesbian, bisexual, and heterosexual women; there should be no sexual contact during any prodromal symptoms that may precede a genital herpes outbreak or during the blister stage of the outbreak. Suppression of lesions can usually be accomplished with antiviral medications, such as acyclovir or valacyclovir, if the lesions are recurrent (see Chapter 6).

There is evidence of HPV transmission between female sexual partners. Ten percent of lesbian women have never had sex with men, yet cervical dysplasia and cervical cancer develop in some of these women. All women need Papanicolaou smears, including lesbian women, according to timetables provided by professional society guidelines. The rate of HPV vaccination in lesbian women (8.5%) is less than in heterosexual women (28.4%) and bisexual women (33.2%), which contributes to health disparities. Administration of the HPV vaccine is critical to the prevention of cervical cancer. Despite recommendations that Papanicolaou testing be performed regardless of sexual orientation, Papanicolaou testing varies according to identity irrespective of behavior. In a national probability sample of who underwent Papanicolaou testing, WSWM had the same odds of testing as WSM only, whereas women with lifetime female partners had lower odds of testing. Those who identified as bisexual also had lower odds of testing.

Trichomonas vaginalis can be transmitted easily between female sexual partners. One study of women attending an STI clinic in the United States noted that *T vaginalis* was the most common curable STI found in this population with a prevalence of 17% in WSW and 24% in WSWM.

Bacterial vaginosis is common among women and according to the CDC, even more common among WSW. It is unknown whether bacterial vaginosis can be transmitted between women. A study from Australia found a 27% prevalence of bacterial vaginosis in women and their female partners; risk factors for bacterial vaginosis were four or more lifetime female sexual partners, a female partner with bacterial vaginosis symptoms, and smoking at least 30 cigarettes weekly. Routine screening for bacterial vaginosis, though, is not currently recommended and testing should be based on symptoms. One approach for a WSW who has symptomatic bacterial vaginosis is to treat her and not her female sexual partner. If symptoms recur, her female sexual partner(s) should be evaluated and treated with consideration of re-treating the index woman. This strategy may also be used for treatment of recurrent or hard to treat vulvovaginal candidiasis, which technically is not considered to be sexually transmitted, but anecdotally, improvement has occurred with treatment of the index patient and female partner.

▶ Prevention of Substance Use

Substance use is higher in lesbian and bisexual women compared to heterosexual women and is especially well-documented for cigarette smoking and alcohol use. A secondary analysis of alcohol, tobacco, and other drug use among lesbian and bisexual women in the American College Health Association's National College Health Assessment revealed that bisexual women had greater odds of using alcohol, tobacco, and marijuana than heterosexual women and lesbian women. In addition, bisexual women had greater odds of using all illicit drugs (except steroids) and misusing prescription drugs than heterosexual women. Furthermore, bisexual women had greater odds of using amphetamines other than methamphetamine, sedatives, and 3,4 methylenedioxymethamphetamine (MDMA; Ecstasy) when compared to lesbians. Lesbians had greater odds of using tobacco, marijuana, sedatives, hallucinogens, and other illicit drugs and misusing prescription drugs than heterosexual women.

Multiple interventions have been initiated to decrease alcohol and other substance use in lesbian and bisexual female youth. In Canada, there were significant lower odds of binge-drinking among lesbian and bisexual girls in schools with longer-established Gay-Straight Alliances. Recommendations for improving substance use treatment for sexual minority persons include providing interventionists with training in LGB cultural sensitivity. There has been no specific interventions outcomes research, however,

comparing LGBT adapted materials with routine materials. Some LGBT clients in these programs find it hard to “come out” to a group that potentially includes members who may be homophobic. Sexual minority women, compared to heterosexual women, with lifetime alcohol use disorders are at heightened risk for concomitant psychiatric and drug use disorders, underscoring the need for substance abuse programs to provide access to individual counseling with mental health professionals.

▶ Cancer Risk, Prevention, & Treatment

Very little is known about the incidence and prevalence of various cancers in lesbians and bisexual women, since sexual orientation has not been routinely included in cancer screening programs and cancer registries. However, emerging data suggest that sexual minority women may be at a higher risk for cancer-related mortality than heterosexual counterparts. Investigators from the Women's Health Study compared sexual minority veterans and civilians to their heterosexual counterparts and found that sexual minority women veterans had a higher risk of cancer-specific mortality. Information from the US National Health Interview Survey showed that lesbian and bisexual women have cancer risk factors, such as tobacco use, underscoring the need for vigilant screening. Since lesbian and bisexual women have barriers to accessing health care and may not see a clinician on an annual basis, any visit to a health care provider is an opportunity to check on cancer screening status (eg, colonoscopy, mammography). There is also recognition that upon receiving a cancer diagnosis, LGBT people face challenges in receiving equitable care throughout the cancer care continuum and may experience cancer differently and have different needs during their care; heterosexual and sexual minority cancer survivors in the UK reported receiving different care. The US National Cancer Care Network Guidelines do not address how sexual and gender minority status should be considered in site-specific guidelines. One qualitative study with sexual and gender minority breast cancer survivors underscored the challenges of disclosing sexual orientation during cancer care and the importance of provider recognition that varying social networks are critical to positive experiences of care provision. The 2017 American Society for Clinical Oncology position statement recommends five action steps to enhance LGBT cancer care and reduce disparities: (1) patient education and support, (2) workforce development and diversity, (3) quality improvement strategies, (4) policy solutions, and (5) research strategies.

All providers need to consider whether their prevention, screening, diagnostic, treatment, and palliative approaches will be equitably experienced by lesbian and bisexual women.

A. Breast Cancer

The literature has been mixed on whether lesbian and bisexual women have a slight increased risk of breast cancer compared to heterosexual women. A 2013 systemic review found the few prevalence studies of breast cancer in lesbians unreliable; however, lesbians do have an increased prevalence of risk factors predisposing to breast cancer, including nulliparity, alcohol use, obesity, and smoking. The literature is also inconsistent regarding the rate of mammography screening in lesbian women; however, a study done in Massachusetts showed that bisexual women were less likely than heterosexual women and lesbian women to adhere to mammography screening guidelines. Lesbian and bisexual women who have breast cancer may not want reconstruction at the same rate as heterosexual women and often find that breast cancer support groups focus on issues for heterosexual women (such as attractiveness to a male partner).

B. Cervical Cancer

Primary prevention of cervical cancer is essential. All females between the ages of 12 and 26 years should receive the HPV vaccine series even if they never have been or plan to be sexually active with men. HPV is transmitted sexually between lesbian or heterosexual partners. The rate of HPV immunization among lesbians is significantly less than for heterosexual women, which creates a health disparity that needs to be corrected. Papanicolaou smears should be part of lesbian and bisexual women's health care at the same intervals as for heterosexual women. Lesbians and bisexual women, however, receive Papanicolaou smears at a lower rate than sexually active heterosexual women, in part because many of the Papanicolaou smears are done in

reproductive health clinics; lesbians who are not sexually active may not access these clinics. In addition, some lesbian patients as well as their health care providers mistakenly think that lesbians do not need Papanicolaou smears. *All lesbians need Papanicolaou smears starting at the age of 21, consistent with recommendations for Papanicolaou smears for all women.*

C. Lung Cancer

Compared to heterosexual women, the rate of lung cancer is likely higher in lesbian and bisexual women due to their increased rate of smoking. The incidence and prevalence of lung cancer, however, has not been determined in this sexual minority population.

D. Endometrial and Ovarian Cancer

Endometrial and ovarian cancer are associated with nulliparity, which is more likely in sexual minority women. Obesity, a known risk factor for both cancers, appears to be more prevalent among sexual minority women. Conversely, the use of oral contraceptives, which is protective against the development of both of these cancers, is lower in lesbian women than in heterosexual women. Vigilance toward and education about presenting signs and symptoms (eg, postmenopausal bleeding, early satiety, unintended weight loss) are important to detect cancers as early as possible. Neither incidence nor prevalence of endometrial or ovarian cancer has been determined in this sexual minority population.

► Prevention of Violence

Compared to heterosexual women, lesbians and bisexual women have higher exposures to violence throughout their lifetimes. Lifetime prevalence of sexual assault may be as high as 85%. In a study of four countries in southern Africa, nearly one-third of lesbian and bisexual women experienced forced sex and assault including “corrective rape” by men as an attempt to change the women's sexual orientation.

The CDC reports that 61% of bisexual women and 44% of lesbians experience rape, physical violence, and stalking by an intimate partner. These rates are higher than similar trauma in heterosexual women (35%). Additionally, approximately 20% of bisexual women compared with 10% of heterosexual women have been raped by an intimate partner in their lifetimes. The rate of stalking experienced by bisexual women is twice that of heterosexual women

and a higher percentage of bisexual women report being afraid of an intimate partner. Despite alarming rates for women of any identity, lesbian and bisexual women survivors of sexual assault and interpersonal violence may experience unique difficulties when seeking assistance. These problems include a limited understanding of interpersonal violence in the relationships of lesbian and bisexual women, stigma, and systemic inequities (such as shelters unwelcoming to this population and staff lacking cultural sensitivity and appropriate training in working with lesbian and bisexual women). Barriers to preventing LGBTQ violence include stigma, systemic discrimination, and a lack of understanding of LGBTQ intimate partner violence.

Community violence is experienced more frequently by LGBT persons. In-depth interviews of 19 Flemish sexual minority victims of violence revealed the use of four coping strategies: (1) avoidance, (2) assertiveness and confrontation, (3) cognitive change, and (4) social support. Applying these coping skills and actively attaching meaning to negative experiences, helped victims of anti-LGBT violence overcome fear, embarrassment, or depressive feelings. The presence of a supportive network was important in facilitating the positive outcomes.

▶ Prevention of Mental Disorders

Lesbians and bisexual women, especially if they are African American, have an increased risk of depression. Many of the health disparities and health risks faced by lesbians and bisexual women, such as depression and cardiovascular risk, have been attributed to Meyer's theory of minority stress. This theory proposes that individuals who identify as a sexual minority experience chronic, additive, and unique stresses stemming from living in social conditions that are characterized by prejudice and discrimination. Therefore, rather than identifying mental health problems as synonymous with a sexual minority identity or stemming from in-born

association with minority sexual orientation, minority stress causes mental health challenges that stem from societal discrimination and stigma borne by individuals with minority identities (and behaviors). A 2013 survey in Ireland of older LGBT people (aged 55 to 80+) revealed that 33% reported having experienced a mental health problem at some point in their lives. Approximately 11% were currently taking prescribed medications. An examination of lesbian and bisexual women veterans from the Behavioral Risk Factor Surveillance System found that sexual minority women veterans were three times more likely than heterosexual women to experience "mental distress." Mortality risk from suicide is also elevated among women with same-sex partners. There is evidence from the National Epidemiologic Survey on Alcohol and Related Conditions—III that bisexual women had greater rates of specific psychiatric disorders than lesbians or heterosexual women. Resilience factors that are protective for mental distress and poorer mental health among lesbian, gay, bisexual, queer and questioning youth and adults in Israel included family support as well as other community-level factors, such as friends' support, LGBT connectedness, and having a steady partner. How parents react to an adolescent's "coming out" has a profound effect on their child's health outcomes. For those adolescents whose parents were supportive, there was less homelessness, depression, substance use problems, and unprotected sex. Interventions for building resilience can be important in achieving a reduction in anxiety and depression. There is some evidence that online friends can serve as a buffer and social support, especially for LGBT youth, although in-person social support appears to be more protective against victimization.

There is emerging evidence that being in a legally recognized same-sex relationship, particularly in marriage, diminishes mental health differences between heterosexual and lesbian, gay, and bisexual persons. In contrast, psychiatric disorders increased among lesbian, gay, and bisexual persons who live in states in the United States that enacted constitutional amendments to ban same-sex marriage compared to states that did not. One study examined the mental health of individuals living in states before (wave 1, 2001–2002) and after (wave 2, 2004–2005) the enactment of same-sex marriage bans in 2004–2005. Among LGB respondents living in states that enacted the marriage bans, the National Epidemiologic Survey on Alcohol and Related Conditions (N = 34,653), revealed that there was a significantly increased prevalence of any mood disorder (36% increase), generalized anxiety disorder (248% increase), any alcohol use disorder (42% increase), and psychiatric comorbidity (36.3%) between wave 1 and wave 2 of the survey, suggesting that living in sociopolitical environments that do not legally recognize same-sex relationships can have deleterious effects on mental health.

► Family Planning

A. Pregnancy Prevention

Comprehensive family planning for lesbians and bisexual women is important to address during the potential reproductive decades spanning from young teens until mid-50s. The majority of lesbians have been sexually active with men at some point in their lives (85–90%), and 30% of self-identified lesbians are currently active with men. Fewer lesbian youth use hormonal contraception than heterosexual female youth. However, on multiple surveys, one of the reasons that lesbians do not follow up for gynecologic care is the assumption by the clinician that they are heterosexual, and the (insensitive) advocacy of birth control in that assumptive atmosphere about their sexuality. But avoidance of unintended pregnancy is a lesbian issue. From multiple studies, the unintended pregnancy rate of female lesbian youth is higher than that of the comparison heterosexual female youth. Unintended pregnancy risk continues into adulthood with one sample from the Chicago Health and Life Experiences of Women (CHLEW) survey reporting 24% of sexual minority women reporting having had unintended pregnancies. The reasons for disproportionate unintended pregnancy rates have not been fully elucidated but may involve discrimination and family rejection leading to higher-risk behaviors, increased alcohol and other substance use, less birth control usage, and multiple sexual partners. Another reason may be attempts to prove one's "straightness" through pregnancy. If it has been determined that the patient self-identifies as a lesbian and is having (penis-in-vagina) sex with men, one suggested question might be, "Are you planning to get pregnant this year?" If the answer is no, this is an opportunity to explain that studies show a higher unintended rate of pregnancy in lesbians and to review effective contraception options. It is also a good time to talk about protection from STIs when having sex with men (ie, discuss condoms). As with any person engaging in penis-in-vagina sex, experts recommend additional contraceptives to condoms, which are only 80% reliable in preventing pregnancy (typical use). Long-acting reversible contraceptives, which are not patient or sexual act dependent and function effectively despite alcohol or other substance use, are especially important to consider. Long-acting reversible contraceptives such as an etonorgestrel subdermal implant in the arm (0.05% annual failure) or either the copper (0.8% annual failure) or levonorgestrel (0.2% annual failure) intrauterine devices are highly effective and typical use is generally equivalent to ideal use.

B. Family Building

Family building should be discussed with all patients, regardless of sexual orientation or gender. Options include adoption (in some countries this option is not open to LGBT persons), co-parenting a partner's child/children, biologic pregnancy, or stepparenting. Lesbians and bisexual women have many options to consider for conception and may ask the clinician for an opinion and to guide them to resources. Many lesbians decide to have inseminations with an unknown donor (some donors sign a release so that the child may contact the donor when the child reaches 18 years old), and some lesbians decide to involve a known sperm donor. Most sperm banks are regulated in regard to the administration of medical history forms, the testing of sperm for STIs, and the performance of genetic screening. Known donors may have risk factors but are not routinely screened for them. It is important for women to be as informed as she can be about the legal implications of each option. In some states and countries, unless the insemination with a known donor takes place in the office of a physician and with legal provisions abdicating familial rights, the known donor has full legal rights as well as financial responsibilities for the offspring. A woman planning a pregnancy should be encouraged to consult with a family attorney prior to conception, and if she is partnered, her partner needs to be aware of her legal rights and responsibilities. Even if they are married, some jurisdictions do not recognize same-sex marriage and may not recognize parentage rights of the couple over biologic rights of the donor. In some states in the United States, married same-sex female couples who conceive children with the use of donor sperm will go through adoption processes to have their full parental rights recognized. Not all US states support the rights of same-sex couples to adopt. In one study of 129 lesbian mothers with 77 index offspring, 77.5% of the mothers were satisfied with the type of donor chosen (36% had chosen known sperm donors, 25% open-identity donors, and 39% unknown donors). Donor access and custody concerns were the primary themes mentioned by lesbian mothers regarding their (dis)satisfaction with the type of sperm donor they had selected.

Access to sperm banks and fertility treatment is not always available to lesbians who are "out." Even in countries where legislation affords lesbians access to reproductive technology, interactions with health professionals can result in homonegative experiences, as reported in the United Kingdom.

Some lesbians who are partnered decide to do "co-in vitro fertilization (IVF)," which is also known as "reciprocal IVF" or "co-maternity" in which one partner provides an egg, it is fertilized in the laboratory with sperm of a known or unknown donor, and then the other partner carries the pregnancy. Many lesbians also engage in stimulating lactation for the non-gestating mother with resources that

stemmed originally from the experiences of adoptive mothers. Health care providers should be willing to support patients in exploring these options. Many lesbians delay childbearing until later in life, and then the issues of fertility, pregnancy loss, and birth defects are increased. There have been many studies on the outcomes of children of lesbians, all of which have been positive when comparing them to children raised by heterosexual parents, despite the stigma the children experience of having same-sex parents. Using the 2011–2012 National Survey of Children's Health data set from the United States, children with female same-sex parents and different-sex parents demonstrated no differences in outcomes (spouse-partner relationships, emotional difficulties, coping behaviors, and learning behavior). There is very little about parenting experiences among women who identify as bisexual and how these findings might differ from experiences of lesbian women.

GAY & BISEXUAL MEN'S HEALTH

Kevin L. Ard, MD, MPH

Kenneth H. Mayer, MD

Included in this section are the health issues of gay, bisexual, and other men who have sex with men (MSM). These men are a diverse group of individuals with unique health needs that stem from their sexual behavior and from the effects of societal stigma and discrimination. This section is devoted to the primary care of cisgender (that is, non-transgender) MSM regardless of their sexual identity. Most health-related research focused on MSM categorizes men based on their sexual behavior as MSM, rather than their self-reported identification as gay, bisexual, or other identities. Although sexual identity is not always congruent with sexual behavior, identity is important to recognize in order to optimize health and health care. When a difference on the basis of sexual identity (for example, gay-versus bisexual-identified men) with regard to health or health disparities is known, this is indicated.

Definitions & Concepts

Sexual orientation refers to a deep-seated sense of one's sexuality that encompasses three dimensions: identity,

behavior, and desire. Sexual identities include gay or homosexual (those who are predominantly attracted to and/or sexually active with members of the same sex), bisexual (those who are attracted to and/or sexually active with both men and women), and heterosexual or straight; however, several other terms may be used, and terminology may change over time. For example, the word “queer,” historically a pejorative term, has been reclaimed by some as a positive descriptor of a nonheterosexual orientation.

The three dimensions of sexual orientation—identity, behavior, and desire—do not necessarily overlap. For example, less than 50% of MSM in one national, probability-based survey identified as gay. MSM who identify as heterosexual rather than as gay or bisexual may be more likely than their gay-identified counterparts to be married to women, foreign-born, of minority race, and of lower socioeconomic status. The incomplete overlap of identity and behavior mean that clinicians cannot rely upon self-reported identity to infer sexual behavior, and vice versa.

Sexual orientation may also change over time or be situational (eg, emerge during periods of limited mobility without contact with women, such as during incarceration). In addition, people may hide their sexual orientation from others, including clinicians, in order to avoid stigma and discrimination. Revealing one's sexual orientation to others is called “coming out”; this process may occur at any point in life and may vary by context (for example, being “out” to family but not coworkers), although the average age at which men and boys come out has been declining and is currently estimated to be in the mid-teenage years.

Demographics

The size of the MSM population in the United States is not known with certainty due to variability in the definition of sexual orientation used in surveys and the possibility that some survey respondents do not disclose nonheterosexual orientations because of concerns about discrimination. Nevertheless, based on available data, it is estimated that 2.2% of American adult men identify as gay, and an additional 1.4% of men identify as bisexual. The proportion of men who engage in sex with other men or experience sexual attraction to other men is estimated to be higher, with 7.3% and 6.2% of adult men reporting some same-sex attraction and sexual behavior, respectively, in one national survey.

Stigma & Discrimination

Although social acceptance of nonheterosexual orientations is increasing, gay, bisexual, and other MSM may still experience stigma and discrimination based on their sexual orientation and/or gender expression, with significant impacts on health. In one national survey of LGBT Americans, discriminatory experiences were commonly reported: 39% of respondents endorsed experiences of rejection by family or friends, 30% had been physically attacked or threatened, 23% had been treated poorly in public, and 21% reported being treated unfairly at work. These experiences may contribute to adverse health outcomes among MSM and other LGBT populations. One model for how this occurs centers

on the concept of minority stress. In this model, stressors such as experiences of prejudice, expectations of rejection, the cognitive burden of deciding whether to come out in different circumstances, and internalized homophobia lead to anxiety, depression, and maladaptive coping behaviors such as substance use disorders and risky sexual behavior. In adolescents, family rejection has been linked to increased risk of depression, homelessness, suicide attempts, illegal drug use, sexual risk-taking, and HIV/STI acquisition. Avoidance of—or delays in—seeking health care due to concerns about discrimination in medical settings may also contribute to adverse health outcomes in MSM.

Health Disparities

Gay, bisexual, and other MSM face health disparities stemming from the biologic aspects of their sexual behavior and/or from minority stress. Because of these disparities, MSM have been identified as a priority population for health-related research and improvement in health care by both the Institute of Medicine and the federal government's Healthy People initiative. These health disparities are exacerbated if young MSM have experienced early life traumatic events, such as sexual abuse or familial rejection.

A. HIV and Other STIs

A difference in the burden of HIV infection is one of most well-described disparities affecting MSM. MSM account for 70% of all new HIV infections in the United States, despite representing a small proportion of the country's population. The high burden of HIV infection among MSM stems in part from the efficient transmission of the virus through receptive anal intercourse, which confers a higher risk of HIV infection than other sexual activities, such as

penile-vaginal and oral intercourse. Role versatility can also uniquely potentiate HIV spread among MSM, since the same person can acquire HIV via receptive intercourse and become an efficient transmitter by engaging in insertive intercourse with HIV-uninfected partners. The origin of disparate HIV rates between MSM and other populations is not solely biologic in origin, however, as societal stigma and psychosocial problems also contribute to sexual risk behavior among MSM. MSM of color face an increased risk of HIV; the CDC estimates that the lifetime risk of HIV infection is 1 in 2 for African American MSM and 1 in 4 for Latino MSM compared to 1 in 11 for white MSM. Racial and ethnic disparities in HIV infections among MSM do not appear to be due to differences in sexual behavior or substance use but rather factors such as lack of access to medical care, lower rates of recent HIV testing among nonwhite MSM, and assortative mixing, (ie, being more likely to have sex with partners from one's own racial or ethnic group).

Beyond HIV, some STIs are more common among MSM. In 2016, 58% of primary and secondary syphilis diagnoses occurred in MSM or men who have sex with both men and women. Syphilis is associated with a high risk of subsequent HIV acquisition in MSM and may serve as a marker for individuals who could benefit from intensive HIV prevention efforts, such as preexposure prophylaxis (PrEP). In addition, an outbreak of ocular syphilis, occasionally resulting in blindness, was reported in 2016, with a majority of cases occurring in MSM. The incidence of gonorrhea among MSM exceeds that among men who have sex with women (MSW) and has increased. MSM also are more likely than MSW to be infected with antibiotic-resistant gonorrhea. Many gonococcal infections in MSM occur at extragenital sites, such as the pharynx or the rectum, where they may be asymptomatic, underscoring the importance of eliciting a comprehensive sexual history, including an inventory of potential anatomic exposures, in order to provide optimal health care to MSM.

MSM also face increased risks of viral hepatitis. Outbreaks of hepatitis A infection have been documented in MSM groups, likely due to anal sexual contact, including oral-anal exposure ("rimming") as well as insertive and receptive practices. Likewise, hepatitis B appears to be more common among MSM than the general population; approximately 20% of MSM have evidence of either current or prior infection with hepatitis B by age 30. This highlights the importance of universal vaccination for young MSM, preferably prior to the initiation of sexual contact. Finally, although hepatitis C is generally not efficiently transmitted via sexual contact, hepatitis C infection has been identified as a problem among HIV-infected MSM and is associated with condomless receptive anal sex, group sex, manual insertion of fingers into the rectum ("fisting"), and recent STIs, which make the rectal mucosa more susceptible to hepatitis C acquisition.

HPV infection, which can cause anogenital warts, anal dysplasia, and anal cancer, is more common among MSM than MSW. A meta-analysis estimated the prevalence of the oncogenic HPV type 16 in the anal canal to be 35.4% among HIV-infected MSM and 12.5% among MSM without HIV. Correspondingly, anal cancer incidence is higher among HIV-infected versus HIV-uninfected MSM.

Studies are underway to determine the optimal frequency of screening for anal cellular atypia and follow-up high resolution anoscopy for sexually active MSM (see below).

Some enteric infections may be sexually transmitted among MSM engaging in anal sexual contact, especially oral-anal sexual contact, and should be considered in the differential diagnosis of gastrointestinal complaints. These infections include giardiasis, amebiasis, and shigellosis. In addition, *Shigella* infections are more likely to be antibiotic resistant among MSM than among other individuals.

Clusters of meningococcal disease among MSM in the United States and Europe have also been reported, most recently in 2016, prompting some jurisdictions to recommend meningococcal vaccination for all MSM. Intimate contact with multiple partners has been identified as a risk factor for infection in some of these outbreaks.

C. Substance Use

Compared to men with only female sexual partners, MSM are more likely to report lifetime recreational drug use; they are specifically more likely to have used cocaine, hallucinogens, inhalants, analgesics, and tranquilizers. In addition, men who identify as gay or bisexual are more likely to smoke cigarettes than those who identify as heterosexual. Although it is not clear that MSM are more likely than others to use methamphetamines, methamphetamine use in MSM communities has been linked to increased sexual risk behavior and transmission of hepatitis C, HIV, and other STIs. Consistent with the minority stress model, experiences of discrimination have been independently associated with substance use among MSM. Several studies have indicated that substance use programs that integrate support for minority sexual identity for MSM can result in long-term successful outcomes.

Clinical Care

Clinicians can take steps to address health disparities affecting gay, bisexual, and other MSM by making clinical environments welcoming, inquiring about social and sexual histories in an open and nonjudgmental manner, and providing preventive care that is concordant with clinical practice guidelines that have been developed for this population.

A. Making Clinical Environments Welcoming to Gay, Bisexual, and Other MSM

Several simple steps can contribute to a friendlier care environment for MSM. These include incorporating LGBT-friendly imagery on posters and brochures, creating and prominently displaying a nondiscrimination statement that includes sexual orientation and gender identity, collecting information about sexual orientation and gender identity routinely from all patients, and avoiding assumptions about heterosexuality throughout the patient care process. For example, when inquiring about relationship status, clinicians should ask male patients about “partners”

B. Mental Health

Likely due to minority stress (ie, growing up in non-affirming societies), MSM experience mental health disorders more commonly than other men. Whether defined by self-reported identity as gay or bisexual or behaviorally by report of sexual activity with other men, MSM have a higher lifetime prevalence of depression and anxiety disorders than men who identify as heterosexual and/or who report sexual activity only with women. Behaviorally bisexual men experience a higher burden of both depression and anxiety disorders, compared to men who engage in only homosexual behavior, in part because bisexual men may not have access to defined communities of choice, like self-identified gay men. The increased prevalence of mental health disorders among behaviorally bisexual men may also stem from dual stigmatization by both the heterosexual and gay male communities, as well as internalized stigma. Among MSM overall, anti-gay violence, community alienation, and dissatisfaction with an idealized body image have all been associated with depression.

or “spouses” rather than “girlfriends” or “wives.” Strategies to make clinic environments more welcoming to LGBT patients are described in the above section, Lesbian & Bisexual Women’s Health.

B. Obtaining Sexual History From Gay, Bisexual, and Other MSM

The core history and physical examination is not different for MSM in comparison to other patients. As with all adolescents or adults, a complete medical history for MSM should include a comprehensive sexual history. Key data to gather include sexual function and satisfaction, the number of partners if the patient is sexually active, and the gender of the patient’s sexual partner(s). In addition, clinicians should determine the types of sexual practices the patient engages in (for example, oral sex, insertive anal sex, and/or receptive anal sex); how often condoms are used, if at all, for the different sexual practices the patient engages in; and whether drugs or alcohol are consumed in conjunction with sex. Clinicians should also establish whether there is a history of STIs because a positive history may have implications for medical follow-up and sexual risk assessment. For example, a recent diagnosis of syphilis would indicate the need for rapid plasma reagin titer monitoring to ensure adequate treatment and would prompt consideration of PrEP due to the association of syphilis with HIV acquisition in MSM. Clinicians may wish to preface discussion of the patient’s sexual history with a

statement indicating that this information is confidential and is important for optimal health care. For example, understanding the types of sex MSM engage in permits clinicians to recommend site-appropriate screening tests for gonorrhea and chlamydia.

Van Wagenen A. Ten things: creating inclusive health care environments for LGBT people. National LGBT Health Education Center. 2015. <http://www.lgbthealtheducation.org/wp-content/uploads/Ten-Things-Brief-Final-WEB.pdf>

C. Preventive Care and Clinical Practice Guidelines

Clinicians can help address health disparities affecting MSM by following clinical practice guidelines that pertain to this population (Table 42–1). The CDC recommends that sexually active MSM undergo screening for HIV, syphilis, gonorrhea, and chlamydia annually and more often if the risk history warrants more frequent assessment. An HIV antibody-antigen assay is preferred for HIV screening because this test increases the sensitivity for detection of acute or recent HIV infection. Nucleic acid amplification testing (NAAT) provides optimal sensitivity for diagnosis of gonorrhea and chlamydia and can be performed on the oropharynx, rectum, urine, and urethra. Although oropharyngeal testing for chlamydia is not

Table 42–1. Clinical practice guidelines pertaining to the care of MSM.

Recommendation	Comments
Immunizations	
Human papillomavirus (4- or 9-valent)	Up to age 26 years
Hepatitis A and B	Consider pre-vaccination serologic testing if the immunization history is uncertain; vaccinate if seronegative
Meningococcal	Recommended by some jurisdictions due to outbreaks of meningococcal disease among MSM
Medications	
Preexposure prophylaxis (PrEP) for HIV	For MSM at high, ongoing risk of HIV infection (eg, condomless anal sex, recent STI diagnosis, HIV-infected sexual partner)
Postexposure prophylaxis (PEP) for HIV	Consists of 28 days of antiretroviral medication following a discrete exposure to HIV
Screening tests	
HIV serology	At least annually, more often if high risk
Syphilis serology	At least annually, more often if high risk
Nucleic acid amplification test for gonorrhea and chlamydia	At least annually, more often if high risk; all potentially exposed sites (oropharynx, urethra, rectum) should be screened, as indicated by the sexual history
Hepatitis C serology	Annually for HIV-infected MSM and HIV-uninfected MSM engaging in behaviors that might expose them to blood (for example, injection drug use or traumatic anal sexual practices)
Anal cytology	For HIV-infected MSM; the appropriateness of anal cytology for HIV-uninfected MSM is under study
Behavioral health (depression, substance use)	At the first clinical encounter, with follow-up screening for those who report behavioral health concerns

MSM, men who have sex with men; STI, sexually transmitted infection.

recommended, MSM should otherwise be screened for these infections at any of the aforementioned sites that may have been exposed during sex, regardless of condom use. First-catch urine and urethral specimens for gonorrhea and chlamydia NAAT in men provide comparable accuracy; thus, there is no advantage to the urethral swab for routine screening. Rectal swabs for NAAT can be self-collected.

CDC also recommends that MSM be screened for chronic hepatitis B infection at least once in their lives and that they be vaccinated against hepatitis A and B. Annual hepatitis C screening with a hepatitis C antibody test is recommended for HIV-infected MSM due to the elevated incidence of this infection in this population and the advent of well-tolerated, curative therapy.

Both CDC and the World Health Organization recommend PrEP for HIV with the fixed-dose combination of tenofovir disoproxil fumarate (TDF)-emtricitabine for MSM at high risk for HIV infection (see Chapter 31). Individuals at high risk include those who engage in condomless anal sex outside of a monogamous relationship with an HIV-negative man; those who have recently been diagnosed with a bacterial STI; and those whose sexual partners are HIV-infected. However, the utility of PrEP is likely low in the latter scenario if the relationship is monogamous and the HIV-infected partner is consistently virologically suppressed on antiretroviral therapy, because antiretroviral therapy significantly reduces the likelihood of HIV transmission through sexual contact. PrEP has been shown in randomized controlled trials to prevent HIV infection in MSM and is addressed in more detail in Chapter 31.

Clinicians who care for MSM should also be aware of postexposure prophylaxis (PEP), which consists of antiretrovirals started within 72 hours of a discrete exposure to HIV and taken for 28 days, and either provide PEP themselves or be able to rapidly link patients to PEP care (see Chapter 31).

While HPV immunization with the quadrivalent or nonavalent vaccines is recommended for all boys and young men up to age 21 years, vaccination is recommended for MSM up to age 26. The HIV Medicine Association (HIVMA) recommends routinely screening HIV-infected MSM for anal cancer with anal cytology; however, this approach has not yet been proven to be beneficial in a randomized controlled clinical trial. In addition, the optimal screening interval (ages at which to initiate and cease screening) and management of abnormal results are not clearly defined. Patients with abnormal anal cytology are typically referred for high-resolution anoscopy with biopsy. Colonoscopy performed for colon cancer screening is not considered a substitute for anal cytology or high-resolution anoscopy because colonoscopy does not assess for cellular abnormalities in the anal canal. Anal cytology screening of HIV-negative MSM is not currently recommended in any national consensus guidelines, although some clinicians perform this screening due to the elevated risk of anal cancer in these men. Large prospective studies are underway in the United States and Australia to attempt to address the questions related to optimal timing of anal HPV screening for MSM.

Finally, clinicians should ensure that MSM are offered preventive care recommended for all individuals, including smoking cessation counseling and pharmacotherapy, screening for depression, and assessment for and counseling about alcohol misuse. Some studies have found that behavioral health programs tailored specifically for MSM are more effective in promoting healthy behaviors than those that are not culturally sensitive.

TRANSGENDER HEALTH & DISEASE PREVENTION

Madeline B. Deutsch, MD, MPH

► Terminology & Definitions

Transgender (abbr: “trans”) people have a gender identity that differs from the sex they were assigned at birth. Gender identity describes a person’s internal sense of gender. Sex refers to the sex assigned at birth typically by the attending medical provider, based on assessment of external genitalia as well as chromosomes and gonads. In everyday language “sex” and “gender” are used interchangeably; however, in the context of transgender people the meanings differ. Gender expression describes the outward manner in which an individual expresses or displays gender, including choices in clothing and hairstyle, speech, and mannerisms. Gender identity and gender expression may differ; for example, a woman (transgender or non-transgender) may have an androgynous appearance, or a man (transgender or non-transgender) may have a feminine form of self-expression. Transgender people who have a well documented and persistent gender identity

that differs from their sex assigned at birth and are experiencing distress as a result of this mismatch, meet the diagnostic criteria for gender dysphoria as described in the *Diagnostic Statistical Manual*, 5th edition (DSM-5).

A transgender man is someone with a male gender identity and a female birth-assigned sex; a transgender woman is someone with a female gender identity and a male birth-assigned sex. A non-transgender person may be referred to as cisgender (Latin root *cis* = near/next to) refers to people whose gender identity and birth sex are the same, ie, non-transgender. Non-binary, gender nonconforming, or genderqueer describes a person whose gender identity differs from that assigned at birth but may be more complex, fluid, multifaceted, or otherwise less clearly defined than purely male or female. Non-binary people may prefer neutral pronouns such as “they,” “them,” or “their.” The term transsexual is an older term that has fallen out of favor and referred specifically to a transgender person who seeks medical interventions. Other related terms include cross dresser, which describes someone who may wear clothing of the opposite gender without a clear identification with that gender, and drag, which describes cross dressing for performance purposes. These identities share some commonalities with transgender people, but are distinct in that they do not involve a core sense of gender dysphoria.

Sexual orientation, which describes sexual attraction and behaviors, is not directly related to gender identity. The sexual orientation of transgender people should be described based on the lived gender; a transgender woman attracted to other women would be a lesbian, and a transgender man attracted to other men would be a gay man.

▶ Providing a Welcoming Clinic Atmosphere

Transgender people may avoid seeking care due to prior discrimination or disrespect in a clinic setting. One in three transgender people report delay in seeking care due to prior discrimination, and one in five report being refused medical care due to their transgender identity. Providing a safe, welcoming and culturally appropriate clinic environment is essential to ensure that transgender people not only seek care but return for follow-up. Each patient should be approached as an individual including preferences of terminology, complex or novel gender identities, and differing desires for gender affirming treatments. Patients should not be expected to discuss their gender identity or transition unless it is relevant to the current visit. Training on transgender cultural sensitivity and health should be provided to all clinic staff and providers. Waiting areas should include transgender-themed posters, artwork, and magazines to indicate a message of inclusion. If gender neutral bathrooms are not available, a clearly stated policy allowing the use of either bathroom should be posted.

Electronic medical record (EMR) systems should include functionality for the recording of gender identity, birth-assigned sex, as well as chosen name and pronoun in the case of a transgender person who has not changed their legal identity documents. Chosen name and pronoun functionality should be displayed in all banners, schedules, and

other viewing screens. Transgender people can be identified within the EMR for those whose entries for gender identity and birth sex differ. EMRs should also allow the tracking of an organ inventory since transgender people may have different organs than are typically associated with the sex under which they are registered in the system. An accurate organ inventory can drive decision support and other functionality for preventive health screening or examination templates.

Transgender people may seek any one of a number of gender affirming medical, surgical or related interventions. Based on research demonstrating positive effects on multiple psychosocial measures, such interventions are recognized as medically necessary by the World Professional Association for Transgender Health (WPATH), an international, multidisciplinary professional organization that publishes widely recognized Standards of Care. Not all transgender people seek all interventions, and some may seek none; the current standard of care is to allow each transgender person to seek only those interventions they desire to affirm their own gender identity.

▶ Medical Interventions

Gender affirming hormone therapy is the primary medical intervention sought by transgender people. Such treatment allows the acquisition of secondary sex characteristics more aligned with an individual's gender identity. The WPATH Standards of Care recognize that hormone therapy is within the scope of practice for primary care providers. The Standards also permit medical providers to prescribe hormone therapy under an informed consent approach without a mental health assessment if the medical provider feels comfortable making the diagnosis of gender dysphoria.

A. Feminizing Hormone Therapy

The goal of feminizing hormone therapy is the development of female secondary sex characteristics, and suppression/minimization of male secondary sex characteristics. The general approach of therapy is to obtain physiologic premenopausal female range estrogen and testosterone levels through the combined use of an estrogen with an androgen blocker, and in some cases a progestagen.

Table 42–2. Feminizing hormone therapy.

Hormone Therapy	Dosage			Comments
	Initial, Low ¹	Initial, Typical	Maximum, Typical ¹²	
Estrogen				
Estradiol oral/ sublingual	1 mg/day	2–4 mg/day	8 mg/day	If > 2 mg is recommend, dose should be divided and taken twice daily.
Estradiol transdermal	50 mcg	100 mcg	100–400 mcg	Maximum available single patch dose is 100 mcg. Frequency of change is brand and product dependent. Patients may find that more than 2 patches at a time are cumbersome.
Estradiol valerate, intramuscularly ³	< 20 mg every 2 weeks	20 mg every 2 weeks	40 mg every 2 weeks	May divide dose into weekly injections for cyclical symptoms.
Estradiol cypionate, intramuscularly	< 2 mg every 2 weeks	2 mg every 2 weeks	5 mg every 2 weeks	May divide dose into weekly injections for cyclical symptoms.
Progestagen				
Medroxyprogester- one acetate (Provera)	2.5 mg orally each night at bedtime		5–10 mg orally each night at bedtime	
Micronized progesterone			100–200 mg each night at bedtime	
Androgen Blocker				
Spironolactone	25 mg orally daily	50 mg orally twice daily	200 mg orally twice daily	
Finasteride	1 mg orally daily		5 mg orally daily	
Dutasteride			0.5 mg orally daily	

¹Initial low dosing for those who desire (or require due to medical history) a low dose or slow upward titration.

²Maximal effect does not necessarily require maximal dosing, as such maximal doses do not necessarily represent a target or ideal dose. Dose increases should be based on patient response and monitored hormone levels.

³Available as standard U.S. Pharmacopia (USP) as well as compounded products.

Clinical endpoints include breast development (often maximum Tanner stage 2/3), reduction of body hair, reduced muscle mass, and female redistribution of body fat.

The most commonly used estrogen is 17-beta estradiol, in pill, patch, or less commonly injected form. The choice of route is based to some degree on patient preference (Table 42–2). Transdermal estradiol has a well-established safety profile based on studies in menopausal cisgender women. Injected estradiol is the least studied route and can be associated with both supratherapeutic levels as well as cyclical levels over the dosing interval. Estrogens should be continued after gonadectomy without reduction in dose. There is no evidence to support discontinuation of estrogen once a patient arrives at a menopausal age. Ethinyl estradiol should be avoided due to thrombogenicity and a lack of need for suppression of ovulation.

The most commonly used anti-androgen is spironolactone, a potassium-sparing diuretic that is frequently used for female hirsutism or adult acne. Spironolactone inhibits both the synthesis of and action of testosterone. In higher doses (100–200 mg orally daily), spironolactone can lead to suppression of androgen levels into the female physiologic range. Common side effects include orthostasis and

polyuria. Monitoring should include periodic assessment of kidney function and serum potassium. Other options for those who cannot tolerate spironolactone include 5-alpha-reductase inhibitors (finasteride, dutasteride), gonadotropin-releasing hormone (GnRH) analog, orchiectomy, or the use of a progestagen. After gonadectomy, anti-androgens can be discontinued.

No studies have been conducted on the role of progestagens in transgender women. Some believe there is benefit to breast development, mood, or libido, and there is no evidence to suggest any harm related to progestagens. Progestagens may be an effective anti-androgen, particularly cyproterone acetate, which is used widely outside the United States as the primary androgen blocker in feminizing regimens. If used, progestagens should be initiated after at least several months of estrogen plus anti-androgen.

The primary risk associated with estrogen therapy is venous thromboembolism (VTE). However, when using 17-beta estradiol at physiologic estrogen dosing, the risk is minimal. Prior studies showing 20- to 40-fold increased risk of VTE involved the use of ethinyl estradiol at doses of up to 200 mcg/day and did not control for tobacco use. More recent data found no increased risk of VTE in transgender

women using transdermal 17-beta estradiol. Thus, transdermal estradiol is the preferred route for those who smoke or with risk factors for or a personal history of VTE.

 Wierckx K et al. Clinical review: breast development in trans women receiving cross-sex hormones. *J Sex Med.* 2014 May; 11(5):1240–7. [PMID: 24618412]

B. Masculinizing Hormone Therapy

The goal of masculinizing hormone therapy is the development of male secondary sex characteristics, and

suppression/minimization of female secondary sex characteristics. The general approach involves the use of one of several forms of parenteral testosterone using an approach similar to that in hypogonadal or agonadal cis-gender men (Table 42–3). Blockade of estrogen is not needed.

Testosterone may be injected or applied as a topical gel or patch. Two studies support the use of subcutaneous (rather than intramuscular) injections, which allow the use of a smaller needle. The use of topical testosterone, or using a weekly (vs biweekly) injection interval can help maintain even hormone levels in those with cyclical mood symptoms or pelvic cramping. Clinical endpoints include the development of facial hair, deepening of the voice, clitoral growth, male body fat redistribution and muscle growth, and induction of amenorrhea by 6 months.

Prior concerns of testosterone-induced hepatotoxicity were based on the use of oral methyltestosterone. There is no evidence to support a concern of hepatotoxicity in transgender men using parenteral testosterone.

Table 42–3. Masculinizing hormone therapy.

Androgen	Dosage			Comment
	Initial, Low ¹	Initial, Typical	Maximum, Typical ²	
Testosterone cypionate ³	20 mg/week intramuscularly/subcutaneously	50 mg/week intramuscularly/subcutaneously	100 mg/week intramuscularly/subcutaneously	For every 2-week dosing, double each dose.
Testosterone enanthate ³	20 mg/week intramuscularly/subcutaneously	50 mg/week intramuscularly/subcutaneously	100 mg/week intramuscularly/subcutaneously	
Testosterone topical gel 1%	12.5–25 mg every morning	50 mg every morning	100 mg every morning	May come in pump or packet form.
Testosterone topical gel 1.62% ⁴	20.25 mg every morning	40.5–60.75 mg every morning	103.25 mg every morning	
Testosterone patch	1–2 mg every night	4 mg every night	8 mg every night	Patches come in 2-mg and 4-mg size. For lower doses, may cut patch.
Testosterone cream ⁵	10 mg	50 mg	100 mg	
Testosterone axillary gel 2%	30 mg every morning	60 mg every morning	90–120 mg every morning	Comes in pump only; one pump = 30 mg.
Testosterone undecanoate ⁶	N/A	750 mg intramuscularly, repeat in 4 weeks, then every 10 weeks ongoing	N/A	Requires participation in manufacturer monitored program. ⁶

¹Initial, low-dose regimen is recommended for genderqueer and non-binary persons.

²Maximum dosing does not mean maximal effect. Furthermore, these dosage ranges do not necessarily represent a target or ideal dose. Dose increases should be based on patient response and monitored hormone levels. Some patients may require less than this amount, and some may require more.

³Available as standard U.S. Pharmacopia (USP) as well as compounded products.

⁴Doses of less than 20.25 mg with 1.62% gel or less than 30 mg with 2% axillary gel may be difficult, since measuring one-half of a pump or packet can present a challenge. Patients requiring doses lower than 20.25 mg and whose insurance does not cover 1% gel may require prior authorization or an appeal.

⁵Testosterone creams are prepared by individual compounding pharmacies. Specific absorption and activity varies and consultation with the individual compounding pharmacist is recommended.

⁶Testosterone undecanoate has been associated with rare cases of pulmonary oil microembolism and anaphylaxis; in the United States, the drug is available only through the AVEED Risk Evaluation and Mitigation Strategy (REMS) Program (<https://www.aveedrems.com/AveedUL/rem/preHome.action>). All injections must be administered in an office or hospital setting by a trained and registered health care provider and monitored for 30 minutes afterward for adverse reactions.

Common side effects of testosterone therapy in transgender men include acne and male pattern baldness, both of which can be approached as in cisgender men. Hemoglobin and hematocrit should be monitored, and if the levels are elevated, consider reducing testosterone dose or changing to a transdermal form or weekly injections to maintain more even levels. Polycystic ovarian syndrome and obesity have been found to be at an increased prevalence in transgender men prior to beginning testosterone therapy. Testosterone is not contraindicated in the presence of these conditions; instead, related metabolic disorders can be managed concurrently.

Olson J et al. Subcutaneous testosterone: an effective delivery mechanism for masculinizing young transgender men. *LGBT Health.* 2014 Sep;1(3):165–7. [PMID: 26789709]

C. Monitoring Therapy

Hormone effects should be monitored both by clinical results as well as hormone levels, if available. Patients should be reminded that results may vary and can take up to 5 years to reach maximal effect; supraphysiologic hormone levels are not likely to enhance results but may incur risks. Note that reported laboratory reference range values may differ depending on the sex of registration of the patient; in general, clinicians should use the reference ranges driven by the current hormonal status of the patient. For example, female reference ranges will be included on automated laboratory reports of a transgender man taking testosterone while still legally registered as female. The interpreting clinician should use the male reference ranges for any tests run on this patient that have sexually dimorphic reference ranges. Tables 42–4 and 42–5 describe general monitoring recommendations, rationales, and

“sex-specific” laboratory values that may require individualized interpretation.

D. Long-Term Health Outcomes

Well-designed, large, long-term studies of health outcomes in transgender people are lacking. The largest existing study of mortality is in a retrospective cohort of 966 transgender women and 365 transgender men who were treated with cross-sex hormones from the Netherlands, which did not control for a number of risk factors. All-cause as well as cardiovascular, cerebrovascular, and other disease-specific mortality among transgender men did not differ from the general Dutch population of cisgender women. Among transgender women, all-cause mortality was 51% higher than cisgender men in the general Dutch population, with the overwhelming majority of the difference due to HIV, drug overdose and suicide; a 64% increased risk (95% CI 43 to 87) in cardiovascular mortality was seen; however, no significant difference was seen for cerebrovascular mortality. It should be noted that this study did not control for tobacco use. Any decisions to provide hormone therapy should include a detailed informed consent discussion and consideration, including recognizing the significant risks of withholding treatment on psychological well being which can have negative impacts on physical health as well as suicidality or substance abuse.

Asscheman H et al. A long-term follow-up study of mortality in transsexuals receiving treatment with cross-sex hormones. *Eur J Endocrinol.* 2011 Apr;164(4):635–42. [PMID: 21266549]

Surgical Interventions

A wide range of gender-affirming surgeries are available to transgender people. These include surgeries specific to

gender affirmation as well as procedures commonly performed in cisgender populations (Table 42–6).

► Cancer Risk & Screening

Several retrospective studies have not identified an increased risk of cancer in transgender people compared to birth-sex matched controls. However, because of the numerous barriers to care as well as to identifying transgender people in clinical databases, underscreening and underreporting are likely. In general, an organ-based approach to screening should be taken. There are no modifications to screening recommendations (or recommendations not to screen) for ovarian, uterine, or cervical cancer in transgender men. Breast cancer screening for transgender men who have not undergone mastectomy should be

performed based on guidelines for cisgender women. The role of screening for breast cancer in transgender men who have undergone mastectomy is unknown and depends on the technique used as well as technical limitations on screening small amounts of residual breast tissue. In transgender women, breast cancer screening using guidelines for cisgender women is recommended, with the modifications starting at age 50 and only after a minimum of 5 years of lifetime estrogen exposure. Screening for prostate cancer in transgender women is complicated beyond the current debate over the utility of prostate cancer screening in cisgender men by the effects of feminizing hormones on prostatic hypertrophy and interpretation of tests of the PSA.

While screening transgender women for pituitary adenoma with serum prolactin levels has been done in the past, this is not recommended in asymptomatic patients since current guidelines for the management of incidental prolactinomas is watchful waiting. Prolactin screening should occur in transgender women with galactorrhea, visual disturbances, or a new headache pattern.

Table 42–6. Procedural interventions for gender affirmation.

Surgeries specific to transgender populations
Feminizing vaginoplasty
Masculinizing phalloplasty, scrotoplasty
Metaoidioplasty (clitoral release/enlargement, may include urethral lengthening)
Masculinizing chest surgery (“top surgery”)
Facial feminization procedures
Reduction thyrochondroplasty (tracheal cartilage shave)
Voice surgery
Surgeries not specific to transgender populations
Augmentation mammoplasty
Hysterectomy, oophorectomy
Orchiectomy
Vaginectomy
Other interventions
Facial hair removal
Voice modification
Genital tucking and packing
Chest binding

► HIV

Transgender women in the United States are 34 times more likely to be infected with HIV than the general population. This disparity is driven by a number of factors, including lack of both employment opportunities and legal

protections in the workplace and elsewhere, all of which can result in survival transactional sex and sex work, and an association between unaffirmed gender identity and high-risk sexual behavior. Based on studies of hormonal contraception, gender-affirming hormone therapy is not believed to have negative interactions with antiretroviral medications, although direct studies are lacking. A sub-analysis of transgender women within a larger study of HIV PrEP with a daily fixed-dose combination of tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg suggested efficacy when taken as prescribed but demonstrated poor adherence in comparison to control MSM. Such findings support the notion that HIV services and programs targeting transgender populations should be developed and implemented distinctly from those targeting MSM,

and that bundling of HIV care with gender-affirming care may improve HIV outcomes.

 - angiotensin II receptor blocking agents in, 465–471, 468–470*t*, 475
 - angiotensin-converting enzyme (ACE) inhibitors in, 465, 466–467*t*, 475
 - in aortic dissection, 480*t*, 496–497
 - arteriolar dilators in, 474*t*, 475
 - beta-adrenergic blocking agents in, 460–465, 463–464*t*, 475, 476*f*
 - in black patients, 460, 465, 475, 477*t*, 478
 - calcium channel blocking drugs in, 471, 472–473*t*, 475, 476*f*
 - in cardiomyopathy, 429
 - cardiovascular/cardiac disease and, 10–11, 373*f*, 455, 458, 459, 459*t*, 465, 475
 - cocaine use and, 465
 - combination products in, 462*t*, 463*t*, 464*t*, 466*t*, 467*t*, 468*t*, 469*t*, 470*t*, 475–476, 476*f*
 - demography and, 476, 477*t*
 - depression caused by, 474*t*, 475, 1088
 - developing regimen for, 475–476, 476*f*

- Antihypertensive drug therapy (*Cont.*):
 in diabetes mellitus, 459, 460, 465, 471, 476, 477
 complication rate/diabetic nephropathy and, 955, 1248
 diuretics in, 460, 461–462*t*, 475, 476*f*
 in elderly, 460, 465, 477*t*, 478
 follow-up and, 478
 goals of, 458–459, 459*t*, 479–480
 heart disease/failure and, 10–11, 418, 455
 nonadherence and, 476, 479
 patient selection for, 458, 458*t*
 peripheral sympathetic inhibitors in, 474*t*, 475
 pheochromocytoma/
 pheochromocytoma surgery and, 1193
 in poisoning/drug overdose, 1582
 for preeclampsia/eclampsia, 480*t*, 824
 during pregnancy, 832–833
 preoperative/perioperative, 49
 in renal disease/failure, 477–478, 480*t*
 renin inhibitors in, 465, 466*t*
 resistant hypertension and, 477*t*
 stroke/stroke prevention and, 455–456, 459, 479–480, 1011
 sympatholytics in, 474*t*, 475, 1596
 thresholds for, 458–459, 459*t*
 in urgencies/emergencies, 479–480, 480*t*, 481*t*
 vasodilators in, 474*t*, 475
- Anti-IgA antibodies, IgA deficiency and, 896
- Anti-IL-12/23 antibody, 665, 670
- Anti-inflammatory drugs. *See*
 Corticosteroids; Nonsteroidal anti-inflammatory drugs
- Anti-insulin antibodies
 in autoimmune/immunopathologic hypoglycemia, 1261, 1266
 in diabetes, 1220, 1221*t*, 1242
 insulin therapy causing, 1246–1247
- Anti-insulin receptor antibodies
 in diabetes/insulin resistance, 1222
 in hypoglycemia, 1261, 1266
- Anti-integrins, 664–665, 670, 673
- Anti-intrinsic factor antibodies, 634
- Anti-Jo-1 antibody, 854*t*, 862, 862*t*
- Anti-leucine rich glioma inactivated 1 antibody, 1021
- Antileukocyte antibodies, transfusion-related acute lung injury caused by, 554
- Antileukotriene agents. *See* Leukotriene modifiers
- Anti-LKM1 (liver-kidney microsome type 1 antibodies), 707
- Anti-Ma2 antibody, 1021
- Anti-MAG antibodies, in cancer-related neuropathy, 1022
- Antimalarial agents, 208–209*t*, 1518–1519, 1518*t*, 1519–1523, 1519*t*, 1520*t*, 1523*t*
 G6PD deficiency and, 521, 1518, 1521
 for lupus/SLE, 123, 855
 for malaria, 1518*t*, 1519–1523, 1519*t*, 1520*t*, 1523*t*
 chemoprophylaxis, 1523–1524, 1523*t*
 non-falciparum, 1518, 1518*t*
 self-treatment, 1523
 severe disease, 1518*t*, 1519, 1520*t*, 1521, 1522
 treatment, 1518–1519, 1518*t*, 1519–1523, 1520*t*
 uncomplicated falciparum, 1518–1519, 1518*t*, 1519*t*, 1520–1521, 1520*t*, 1521
 rabies vaccine and, 1400
 resistance to, 1518, 1519, 1520, 1520*t*, 1521
 for rheumatoid arthritis, 851
 Anti-MDA5 antibody, 862*t*
 Antimetabolites, 1617–1618*t*
 Anti-Mi-2 antibody, 862, 862*t*
 Antimicrobial chemoprophylaxis. *See also*

 enterocolitica, 599*t*, 600, 1313*t*
 pestis, 1319*t*, 1480
 Yohimbine, toxicity of, 1597*t*
 Yttrium-90 ibritumomab tiuxetan, 544
 YY1/T372R mutation, 1262
 Z score, 1171
 Zafirlukast, 261*t*, 264
Zaire ebolavirus, 1410, 1411
 Zaleplon, 1067*t*, 1102, 1598
 Zanamivir, 1379*t*, 1423, 1423–1424, 1424,
 1425, 1426
 ZAP-70, 541
 ZEBOV vaccine, 1411
 Zenker diverticulum, **626**
 Zeta-associated protein (ZAP-70), 541
 Zidovudine (AZT), 1363*t*, 1366. *See also*
 Antiretroviral therapy
 with lamivudine, 1366
 with lamivudine and abacavir.
 See Trizivir
 myopathy caused by, 1062, 1350
 for prevention of HIV transmission
 to fetus/newborn, 836, 1358
 postexposure/after needle stick, 1359
 Zika virus, **1417–1419**
 pregnancy and, 812, 815, 1418
 screening blood for, 553
 Zika virus vaccine/vaccine development,
 1418
 Zileuton, 258*f*, 261*t*, 264
 Zinc
 parenteral nutritional support and,
 1290, 1293*t*
 toxicity of, 1597*t*
 for Wilson disease, 726
 Zinc transporter 8 (ZnT8) antibodies, in
 diabetes, 1220, 1221*t*, 1242
 Ziprasidone, 1081, 1081*t*, 1082, 1082*t*,
 1084, 1084*t*
 for aggressive/violent behavior, 1104
 overdose/toxicity/side effects of, 1082*t*,
 1084*t*, 1592
 Zirconium cyclosilicate, for hyperkalemia,
 908
 Ziv-aflibercept, 1623*t*
 ZMapp, for Ebola viral disease, 1411
 ZnT8 antibodies, in diabetes, 1220, 1221*t*,
 1242
 Zoledronate/zoledronic acid, 1156, 1168,
 1173, 1179, 1673, 1676*t*. *See*
